A STUDY OF THE SOCIALLY MALADJUSTED*

BY L. PIERCE CLARK, M.D.,

NEW YORK.

IT is unfortunate even in a partial abandonment of a specific classification of mental disorders that our discriminative judgment upon the exact nature of the defect under investigation should suffer. By abandoning a definite classification, the critical faculty is likely to fall away and the results become unsafe for sound clinical estimates. On the other hand, if we follow a too rigid system of nomenclature, the scope of scientific inquiry is often narrowed and our clinical studies of mental phenomena seem unnatural and one-sided.

This dilemma is signally illustrated in considering the life reaction of socially maladapted persons. Some investigators lump this whole group under the broad designation of psychopathic personalities and feel that they have really solved the condition scientifically. Others maintain that the group may be properly designated high grade feeble-minded, and that the individual is a normal dull person with antisocial tendencies or that he is a psychopathic constitutional inferior. But there are not a few psychiatrists as well as many intelligent laymen who still doubt whether so-called constitutional inferiority is a sufficiently sharply defined entity in mental science to warrant its separate consideration from the moron of the feeble-minded class on the one hand, and the atypical group of dementia præcox on the other.

However, practical issues in mental hygiene must be met on the basis of their occurrence, and a large group of adolescents present a distinct social problem in which the neuropsychiatrist is increasingly called upon for aid. Any classification of the socially maladaptive, with or without intellectual defect or with reactions similar to the præcox, fails of large utility in any practical issue. With a great show of reasonableness some have argued that these pathologic personalities vary insensibly from the normal individual with slight, benign defects of social maladaptation during adolescence to those with the most malignant, enduring intellectual and emotional instability, and that no classification for the group is possible or even desirable,—they seem satisfied simply to call such morbid personalities the socially unstable. Considering the foregoing, one is impressed that the time is not yet ripe for the use of any sharp distinctive term for the various phases of social maladaptations.

After general consideration of the nature of the constitutional psychopathic inferior and the general system for care and training of such persons, some widely variant illustrative cases will be given. In considering the restricted few of the constitutional psychopathic inferiors, if a psychologist has been first consulted we find the subject has frequently been classed as a normal dull person, possibly two or three years retarded in one or more mental tests, but not in all. The psychologic test of the practical judgment usually presents marked defects, often grading only as high as the twelfth or fourteenth year and sometimes falling several years below that age. In addition to failures in practical judgment, they show defective manipulation and generalization of specific tests and subjects. There is a lack of self confidence in the examination and a half-hearted attempt to correct the simple faults. The tested subjects lack grit to stick at the individual problem and often grade much lower owing to an inefficient arousing of determination and will to accomplish the required test. The mental development is almost always more asymmetric than the average person's of the same age and opportunities. In the opinion of the more formal psychiatrist the same person is often thought to be a potential præcox or a moral imbecile owing to his instability of emotional control.

These unstable persons form a large class of all sorts of social and business misfits. The main practical defect is evidenced in a weakness of will in all the human activities. Though the intellectual endowment may be good in a superficial estimate, it is easily shown in the majority of cases to be mediocre. Sufficient descriptive knowledge of this group has been made for us to summarize them: Often they are keen observers, are vivacious and know how to use their own limited intellectual powers to the best advantage. On the other hand, they lack energy for continuous work, soon grow weary and are unable to complete any course of education, their knowledge being superficial and fragmentary. While their talents often arouse great expectations, they remain unfulfilled on account of their inconstancy, unreliability, and lack of will power. Higher intellectual development is defective; conception is confused, and judgment is immature and one-sided, while their interests center around frivolous pleasures and they do not respond to the more serious side of life. There in often a tendency to build air castles and to day dream. Emotionally they show abrupt changes—at times elated and confident, and at others spirit-

*Read before the American Neurological Association, June 3, 1920.

less, sensitive, or pessimistic. There is usually an increased irritability, sensitiveness, and peevishness. Although they are generally harmless and good-natured, they are dominated by the most pronounced selfishness; they are inclined to submit to privation but demand comfort and luxuries, regarding restrictions as a personal insult. They lack perseverance and power of resistance and energy, which usually become evident as soon as they are deprived of home influences. At school they are considered pliable, unstable, and easily led. As soon as they have to stand on their own feet they are helpless. Since work is not agreeable, they often change, hoping to find a more ideal occupation. They excuse their unproductiveness in various ways, never attributing the cause to any fault of their own. They are usually unashamed of being dependent on others for support, and believe circumstances justify their conduct. Even though their earning capacity is small, they are careless with money, buying useless articles without thought. They readily yield to temptation, and when placed under guardianship become slack, indolent, and spend their time with loafing and useless fads. In bad company, they take the course of easiest resistance, drifting into all sorts of degenerate and criminal types. The instability first becomes evident so soon as these individuals encounter some difficulty in their lives. Many of these unstables are gradually forced into lives of vagabondage by their congenital instability and not by unusual circumstances. The same condition is shown to exist in the offspring of well-to-do parents, who, notwithstanding an apparently good endowment and education, continue to be unstable. One rarely fails to find in the family stock traces of degeneracy.

It is at once obvious that we are not dealing with a special type of moron, nor is the condition very closely allied to dementia præcox. However, our main concern here is to acquire a more intimate knowledge of the essential emotional defects and determine if possible a less clumsy method of dealing with such individuals. In everyday life the final termination of the career of these constitutional inferiors is to swell the ranks of vagabondage of high and low degree and the ne'er-do-wells shown in alcoholic and sexual excesses and specific antisocial tendencies to steal, lie and swindle. Not a few have short episodes of mental confusion, hallucinosis, or paranoidal ideas of persecution. The latter in our outside sanatoria or asylums, as soon as the extra stress of life is withdrawn, quickly recover from the mild mental episodes and are then easily differentiated from the more malignant deteriorating mental disorders such as the præcox group. In more definitely unstable subjects of the lower classes the method of disposal is easier, but perhaps in the long run is no more satisfactory than in the milder types which occur in the higher strata of life. For several years a large number of the latter have come under my observation requiring a practical judgment of what disposition should be made of them. It is not sufficient to recognize that the real defect is an inherent one and that a cure, so-called, cannot be expected. Neither do we get very far to make the general statement that each subject must be considered upon the special type of defect disclosed.

What are some of these defects and just what may we do for the individual? We may first dispose of the generalities fairly well known and discuss the good and bad points of each. It is known if the defects are not great, a proper regimen of training may help. In order that one may establish proper pedagogic reconstruction, certain facts must first be recognized not ordinarily taken into account. Society immediately takes an unfriendly and uncharitable attitude toward one stigmatized as a public confessant of wrong-doing. In consequence we do not adopt the frank and open plan of dealing with the situation, which causes these individuals to note the hypocrisy in such an attitude and adds fuel to their innate distrust of the general currency of moral honesty. Inferiors are apt at sophistication, and they hold their innate delinquencies are not less reprehensible than the insincere attitude which parents and physicians take toward them. If the weak and vacillating will has given way to an uprush of primitive desires to steal, lie, or indulge in excessive or forbidden sexual acts they hold that either they were justified under the circumstances or they are permissible to those who wish to be non-conformists to current social customs.

Inasmuch as the parents, and not the socially maladaptive individuals themselves, are seriously concerned by the attitude of society, the latter, hardened by flagrant delinquencies, often "sit tight" and nonchalantly taunt those sincerely interested in their welfare with the query, "What are you going to do about it? The dilemma is not one of my own choosing or concern." If such persons could be counted as legally insane, commitment and sanatorium care would then be possible. Social policing by camouflaged tutors and companions is difficult, and a game in which the trump cards are generally in the inferior's hands. Supposing the pursestrings are held by the parents or relatives, usually the training is apt to degenerate sooner or later into a system of coercion by bribery. The régime practically simmers down to a system of "We will give you so much for this or that task, and if you comply with obedience, this privilege or emolument will be granted." All this time the parents and relatives hold that society in general, and too inquiring friends in particular, must not be permitted to guess the true state of affairs. Even professional advice is often sought surreptitiously, and anything like a fair and open policy outside of a reform school or occupational sanatorium seems impossible. One may therefore say that all attempts to disguise the real issues to be set right by their very nature are doomed to failure. The régime, even though it provides proper tutoring and companionship of the trained attendant, if not backed by institutional discipline with mutual cooperative management, is next to never adequate or successful. Therefore absolute candor tempered with kindly but firm sympathy constitutes the necessary atmosphere for the care and training of constitutional inferiors.

We shall consider a series of cases which conform definitely to the classic type of psychopathic

constitutional inferiority. Cases I and II were brought under observation on account of precocious and irregular sexual delinquencies; case III for the same faults, but more definitely for stealing and a general record of criminal acts and tendencies.

CASE I is that of a girl now in late adolescence, born of fairly healthy stock. The mother is, however, quite neurotic. An older brother is a cripple from poliomyelitis and a younger sister is less but similarly afflicted. Our patient was born normal but had a severe attack of eczema for the first two years, to which affection the mother ascribes the child's delay in walking until two years of age. At seven a slight curvature of the spine developed or rather became more extreme, thought to have been congenital. Even as a small child she exhibited a good deal of slyness and dexterity in extricating herself from difficult situations. As a baby she was excitable, especially at play, but cried little when annoyed or injured. She was rather a stoic and relied upon her own ability to get out of things and confided in none of the family. She showed no affection toward anyone. Even as a small child she was selfish and cruel in social contact with other children, and made cruel or hurting remarks in quick retaliation to anyone who wounded her feelings. She was therefore not taken into the girl group and was more feared than otherwise. In kindergarten at five years she showed poor attention. In her advanced education literature, history, and studies that gave power for colorful recitation and dramatic effect appealed to her. She made rather vague attempts at lyrical verse, and did fairly well at coloring and drawing, but her taste in these led more or less to the peculiar, odd, or unusual. She soon showed a decided will to learn what she liked and paid no attention to the other subjects. She says, "My school life was mostly a bore. I not only did not study what I did not like but I could not even understand or retain the subject matter." Thought was always logical but practical judgment seemed never to have been developed. She possessed no apparent realization of the ordinary social adjustment to which her playmates took heed. Her attitude was not a stubborn or resistive one, but rather one of negligence and callous disregard for social custom. Her childish interest in art gradually developed into an intense concern of the gruesome and morbid. She seemed fascinated by ghost stories, sordid and lurid tales of murder, accidents, and catastrophes. When she had reached her tenth or twelfth year she had rather egoistic views and seemed in need of constant excitement. She cared much for dress but gave little real or continued care to her person nor did she treasure her possessions of dress and adornment. Efforts to open her mind to these little defects of character made no apparent impression. At first they were received with an attitude of indifference; later they were tolerated with signs of boredom but not deep annoyance. When things went wrong she blamed others or shrugged her shoulders and gave no heed. She was very courageous in standing any amount of pain or physical discomfort. At puberty she began to exhibit some superficial sociable traits but this was shortlived. She has never had any intimate friends nor made any attempts to more than keep would-be friends as acquaintances. She has never had any regard for money and spends it foolishly. Efforts expended to make her realize this defect are met first with cruel retorts, then sullenness, and finally end by her assuming an attitude of suspicious slyness. While her jealousy within the family is shortlived her enviousness has only known the bounds of selfish desire. She assumes an injured attitude in gaining her own ends. She has always felt above her environment and looked forward to the time when she could go her own way. As a young girl in a summer camp she was considered a disturbing factor because of her vicious attitude toward rules and conventions. Being considered rather as a bad example she was sent out of two such school camps. Her power for harm on the whole in the schools seems to have been circumscribed to the weak and superficial characters like her own, and consisted mostly of slight dilatory digressions of conduct. Later, in conjunction with a similar male character, she planned a whole series of confidence games, so ably planned that they were detected and frustrated. In late adolescence, balked in her ambition to study for the stage and become an "emotional" actress, she carried out a personal social dilapidation which ended in a marriage forced by the parents, she concurring under a false assumption on her part of an existent pregnancy. Discovering that he had been tricked, the groom refused to live with her. The possible scandal entailed made the parents of both willing to agree upon a divorce. Our patient suffered a short episode of temper and revolt in which she declared, à la Ibsenesque, "I am determined to have my own way. There is no power under Heaven that will deprive me of living my life as I see fit. If mother stands in my way I will kill her. I have never been understood by anyone, least of all by my mother. I never want to see her again and want nothing to do with her. I have always hated her."

At present we have a young woman of medium height, of comely though not prepossessing appearance. Her features are regular but a rather prominent nose has always given her much concern. She arranges her hair in a rather extreme style, and has used rouge for several years. Her apparel, largely of her own choosing, is neat, a little overdressed in color and fashion. She sat quietly and replied to questions with a slightly bored manner. She rarely smiled but was not without a certain sense of humor even when the incident recounted was to her own disparagement. Although she was reared in a small university town she made little or no use of its possible social advantages. With keen animation when taxed with the fact she said, "You see, my home town has always bored me. I sent flowers to myself and wrote friends improbable tales about my good social times because I had a foolish desire to make life seem more worth living. The people are hopelessly engrossed in small town affairs, and the university set are rigid and pedantic in the extreme. There are practically none who understand or experience any free social or human relations. As to the environment at home, mother never seemed to have time or inclination to talk freely with me. I was so ignorant when in the high school that the other 'wise' girls used to stuff me with impossible tales about all phases of life. Gradually I pieced things together and fashioned my own attitude and opinions about people, and what their aims in life really were." After an apparent struggle to hold back something she finally added, "I really never fitted into my home or the social life. Not until I got away to school and to a larger city did I really get to know what life was." Then followed a fairly clear account of her emotional life, told without apparent exaggeration or deep feeling. She even mentioned her "shocked" attitude when she learned that other girls fabricated, falsified their expenditures to gain a larger allowance, and even entered into questionable relations with men. "Yet," she adds, with little emotional reaction, "I can only partially explain my own conduct. A part of it seems reasonable and logical, and other parts, while technically wrong, I feel no twinges of conscience over. My attitude may seem queer, but I was born that way. Perhaps my life is wrecked, in a sense, but a freer life, preferably on the stage, is the one I should prefer. I never hope to become a great actress. I simply want to play in stock and make my own living and go my own way." When asked if she really understood the amount of work necessary even to play minor rôles, she seemed unconcerned and indifferent to the importance of dramatic study necessary to gain any good paying position in the theatrical field.

Her psychologic test was as follows: In the Stanford Revision of the Binet-Simon tests, she passed all the tests of the ninth year, which is therefore her basal year. In the tenth year she failed on the Healy-Fernald Puzzle. She made repeated attempts, and when urged to try again repeated her mistakes, making random moves and did not succeed in fitting the objects in their places. She was able to do it without error after one demonstration, and expressed chagrin at having failed in what she called such a simple thing. In the twelfth year level she failed on practical judgment test. Her performance was equivalent to that of

an eight year old child. At the fourteenth year level she was able to do three of the six tests, while she did four of the six tests of the twelfth year, which is equivalent to the performance of the average adult. She succeeded in those tests that involved the understanding and use of language. Her marked failures throughout the tests were on situations involving the use of practical judgment, manipulations, and generalization. Her performance was characterized by lack of self-confidence, and an attitude of failure. Because of this her score may be somewhat lower than she could make if these emotional elements did not operate. In the Trabue Language Scale C, she made a score of 17, equivalent to the fourth year high school work. In the Mixed Relations (language) test, she scored 117; the average in this test for Barnard freshmen is 119. Her attainment in the mechanics of arithmetic was about equal to the average nine year old child. She failed on simple examples involving the use of fractions. As a general summary, her development is asymmetrical. She did well in tests requiring the use and the comprehension of language, and her performance is equivalent to that of the average adult. The tests indicate that her highest development has been reached along lines involving the comprehension and the use of language. Her intelligence quotient of 89 indicates that her general grade of intelligence is equal to that of a dull normal person.

Remarks.—We have here the detailed account of an abnormal personality in which a certain degree of intellectual deficit is in evidence, but by far the greater fault is in the primary endowment of the emotional instincts and their weak and asymmetric development. Undoubtedly a more painstaking memory training with many artificial helps would have brought about better results in later life. The various camps and schools aided little, not because they were wrong, but because the constitutional inferior cannot unaided lay hold of such advantages. Just as the normal intellectual march has to be slowed for the mentally retarded pupil so here the social adaptive teaching has to be more concrete and detailed to be of great advantage. The slyness and aloofness of early childhood, the weak will evolves into a vicious striking out to protect the growing demand of a need to accept the emotional hints of the girl group training without giving way to antisocial reactions. An intensive desire for self-pleasure was imperfectly yielded to the group consciousness; this entailed poor comradeship. Balked by an inadequate and unsatisfying environment the girl kept her love and life interests centered on herself, in which a self abandon or a shut-in personality would seem to be the alternative. The former was chosen at the first instinctive appeal that was made. The step once taken, a superficial restraint by parental discipline falls away and our subject only elects to lead the easier way or that which, with a foreshortened emotional grasp, she believes will give her what she craves—change, excitement, and an opportunity to gratify sensual pleasures for the moment. The problem of the proper pedagogics here is not simple. The opportunity has been already so delayed and the mental struggle may be said to be almost over. The primary need, of course, is to change the entire environment and determine whether under a new system the crisis of adjustment may not be reopened. Under this plan it may still be possible to make a better social adjustment more acceptable to current standards. The strongest advantage is that nothing essentially vicious was undertaken until the love life was brought to the fore. Under a better environment and training, private tutoring and a normal living régime the love-attachment may find a safer lodgment. While a certain strength of character must be requisitioned to live down the indiscretions of the past, yet in private life they are not so infrequently exhibited as many of us are led to suppose. The good as currently regarded in everyday life has no talismanic potency not often equally matched by other attributes, though the minting is not purified gold.

After a conference with the parents, they decided the best method of handling the situation was to temporize, for the time being at least, by sending this girl unsupported by an experienced tutor to the home of distant relatives for several months' "rest and change of scene" and to undertake a definite system of training and education some time in the future, say in six months. Meanwhile the girl naively remarks, "Why, in four months I shall be twenty-one, and then I can do just as I please. I will then go on the stage *by one route or another.*" Neither the parents nor she apparently realized the obvious implication or import these statements bore.

CASE II is that of a girl in middle adolescence whose unconventional sexual acts caused the parents their first great alarm as to her mental condition and the need of mental examination. She was born of very neurotic stock. The maternal grandfather was practically insane although a man of great prominence and ability. The maternal uncle was a convicted homicidal paranoiac. A paternal aunt is a constitutional inferior. The father and mother are of the neurotic type. The patient is an only child. She was considered a jolly, robust, hearty sort of a girl of whom every one seemed fond and she herself was keen for social life and various sports. On the surface our patient was judged to be without physical or mental defect other than a certain wilfulness. It was noticed, in an indifferent sort of way, that for years she got on poorly in her school work and showed poor capacity to develop logical thought. On a precise inquiry after the social catastrophe the following personal history was produced:

She was precocious in physical development, walked at eight months but did not talk plainly until nearly two years of age. In part the delay in speech was due to changes in governesses who spoke different languages. She was a lively, energetic child, high strung and nervous from birth. She had tantrums and still exhibits such temper reactions in a mild form. At five years without apparent cause she had a mild attack of St. Vitus' dance. Her physical health, however, improved on removal of tonsils and adenoids. Irregular eruption of teeth called for a degree of orthodentistry. A visual error in refraction was corrected. She was always "finicky and notional" about foods and odors. At eleven years of age she was placed under the discipline of a large private school. It was then noticed that she was dull in most of her studies and that she made no great effort to master them. She merely rebelled at learning and was excused; she repeated grades and finally was allowed to drop out after four years of trial in the normal grades. She says, "I've had lots of tutoring in different subjects. but it doesn't do the least good. I can't put my mind on study. I never really learned anything well. If I could manage to get through for the day it was all I cared for. Every now and then I try for a few weeks, then get discouraged and give up. I did well in mathematics (she does not understand simple fractions, and should according to age be taking advanced algebra). I loved drawing (she has no real ability to draw even simple objects and confined her attention to color work and crude clay modelling). Literature

and English are my best subjects (she is not able to spell correctly and cannot write a simple composition). I did well in history." (She is interested only in the stories of the subject and failed in an examination.)

This girl had to be cajoled and bribed to do any definite task at home and gave her entire attention to having a good time. Things that required little mental effort she did by fits and starts. She never planned with foresight, was never punctual and had no sense of family or social responsibility. She liked the new and bizarre. She was fond of animals, but so soon as she tired of them she neglected them. One day she would bubble over with enthusiastic desires to engage in all sorts of activities and the next was spiritless and pessimistic. Her keenest desires were centered upon clothes yet she never had any initiative in their selection or took care of them. Physical pain and discomfort she bore stoically. "When I am crossed at home," she said, "I want to take my belongings and leave home and make my parents spend the rest of their lives in sorrow and repentance for treating me harshly. I've often thought of suicide to accomplish the same result." As an apparent defense to feeling timid with strange children she would be rude and push them out of her way. In an imaginative way she day-dreamed of a world without effort. "I imagined myself a very brave person who was to be decorated for something very remarkable, or for great feats in sports. Then I thought I would become an opera singer, but when I learned they had to do so much practise and were often fat and gross looking I dropped that ambition."

In a mental test by the Stanford-Revision of the Binet-Simon Test her basal age was shown to be twelve years, and a mental age of thirteen and a half years, giving her an intelligence quotient of 87, which brought her into the group designated by Terman as dull normal persons. This includes children who would not, according to any of the commonly accepted standards, be considered feebleminded but who are so far below the actual average of intelligence among races of European descent that they cannot make ordinary school progress, or master other intellectual problems to which average children are equal. They will usually be found able to reach the eighth grade, but ordinarily only after from one to three or four failures. They make up the group of children who are placed in special (not ungraded) classes in our public schools.

In the Trabue Completion Test this girl made a score of fourteen points, which is the performance for ninth grade children or children of fourteen years of age. In the word-building test she averaged up to a child of eight years and showed inability to make new combinations from familiar forms, lack of ingenuity and power of imagination. In the Induction Test (finding a rule), which is regarded as a genuine test of the intelligence by Terman and which brings out the ability to generalize from particulars, this girl was unable to find the rule and therefore completely failed in it. As might be expected, her best performance was in those tests requiring the use of language, such as the interpretation of fables, definitions of words, problems of fact, etc. Her knowledge of formal grammar, however, was limited, and in arithmetic she failed on fourth grade problems. She displayed a childish, naive attitude toward the tests and was anxious to do well, but if she thought a test was difficult she was inclined to give up easily. She lacked self-confidence and gave the general impression of being very immature mentally for her age.

It is interesting and important to note the attitude which the inferior assumes after a rather exhaustive analysis of the problem and the general situation has been explained. For instance, our subject was either sullen or assumed a gloomy introspection with slight eruptions of annoyance and petulance afterward. She soon sought an argument with the mother upon the kind of training a young girl should have. She disagreed with all the principles the mother laid down. She said, "I only wish to be original and live in my own way. There is no sense in your proposed plan. I must have only the sort of training that appeals to me; I must have no hard and fast tasks and should be allowed to do things so long as they do not bore me." When asked what her plan would be she said, "To go about with many people and have much going on—music, dancing, and to see the soldiers." Her regard for people whom she met was merely superficial and to laugh and pass some trite remark was quite sufficient.

It is important to recognize that the mental conflict—to assume an entirely different and normal line of social adjustment—occurs very early. At the time when the inferior has already publicly exhibited a social transgression the attitude has already become habitual or chronic. Hence training must be along the most fundamental lines and not solely upon the particular acts which have been glaringly in opposition to social custom. In a burst of friendly confidence with her tutor our subject said, "I remember several years ago it occurred to me that I might do differently. When I was told of my faults I first thought I would force myself to assume a different feeling and attitude. Then I finally felt, what's the use. There was a desire to relent and set things right and yet an equal desire to master my own affairs. Each time I let things go and was not frank it became easier to keep my own counsel. It got to be actually painful to suppress doing any pleasurable thing."

At a family conference it was decided to place this girl with a tutor companion to carry on and make good her previously neglected school work and to teach and mould her toward a better insight into her defects and thus bring about more stability of character. This effort was successful in part. The flighty periods and revolt from customs and rules were less frequent and disturbing. Her school work was much improved and her conduct was much more natural and consistent; but the depth of real insight never greatly increased. The girl learned and submitted to life discipline as a necessary part to be played, but deeper states of mental unrest gave evidence of discontent smouldering near the surface. Petulance, daydreaming, and periods of conscious blocking of the will also became more frequent. After several months of special policing and tutoring away from home the girl began playing the physician, the tutor, and the parents against each other and finally succeeded in inducing the latter to believe that the real trouble was physical, necessitating special hospital treatments and one or two operations. However, when these were finished, the issues were quite the same. Then a series of special convalescence consisting of rest and recreation was arranged. These at last having been disposed of, a new inventory by another neuropsychiatrist was requisitioned. In her sly, shrewd manner the girl is much interested in the new hopes and vistas that have opened up in the present Fabian policy which she seems to have stumbled upon by accident. Undoubtedly she is on her way to rationalizing ideas to explain her peculiar temperament and the kinds of special nursing she requires toward making a proper life-adjustment. The problem at present is too intricate to even foreshadow its final outcome. One might "guess," however, that if some real emotional appeal, either through love or religion, does not correct the main faults which are innate and bring about a life compromise, this girl is on the way to serious dilapidation in all fields of personal activity. When these occur undoubtedly the relatives will arrive at the conclusion that the causes were exogenous and beyond remedy at the beginning. At any rate, the final tragedy may serve as an excellent illustration of the inadequacy of a divided and shifting responsibility in handling such a problem.

While both Case I and II manifested antisocial tendencies, the first was simply weak in personality type, while the second had a more stubborn determination to follow out her main desires. We shall consider briefly a type of psychopathic inferior with marked criminal tendencies.

The psychopathic delinquent as a clinical entity was recognized as such earlier than the simple unstables. The intellectual faculties of such, recently carefully studied as a group by Glueck, Healy, and Fernald, was first described in 1835 by Pritchard as a form of *moral insanity* and later

by Lombroso's school as the *born criminal.* The main designation of this particular type of psychopathic personality is the apparent normal development of the intellectual faculties within the limits of practical life. The subjects appear normal in ordinary conversation, comprehend well, and acquire a certain amount of knowledge and experience which they exploit with a certain degree of cleverness. There is no memory defect and they are fairly logical in thought. Their views of life are narrow and distorted. In common with the simpler types heretofore given they are unable to perform exacting intellectual work. They lack the capacity of proper reflection and foresight. They also fail to carry accumulated experience as to right behavior and conduct beyond the immediate present. In earliest youth (six to eight years) there are conspicuous moral defects, there is a lack of sympathetic comradeship shown in cruelty toward playmates, and general unresponsiveness to parental or home kindnesses. Later they develop pronounced selfishness. They lack a sense of personal honor and proper affection toward relatives. Attempts at normal education are fruitless, as love and normal ambitions are lacking. Continued force alone is able to keep such individuals from manifestations of unbridled selfishness. Even then after a time this corrective restraint is met by an outwitting cunning and duplicity. Deceit, callousness, stubbornness, and a disposition to lie are added soonor or later. Personal gain only is able to keep such individuals out of difficulties for a time. Their egotism is manifested in braggadocio, vanity, idleness, foolish prodigality, and often weak sentimentality. Usually there is not only little resistance to temptation of various sorts, but there is emotional irritability and positive determination to follow an impulsive and vicious mode of living. As children these individuals shock conventional parents by selecting playmates of an inferior sort, and indulging in petty larcenies and peculations. They wander from one type of discipline to another until they manifest open and flagrant criminal tendencies. They then find themselves thoroughly out of touch with the social customs of their station and have no insight that the essential fault lies within themselves. They often think they are but passing through kinds of experiences that lead to martyrdom. They become sophisticated in conversation and cite instances where others "get away with the goods" in supposedly respectable walks of life. As a class they are usually cowardly and not inclined to open violence, and maintain an attitude of passive opposition and treachery. If their antisocial acts escape exposure or checking they pride themselves on their performance and show an increasing desire to perfect themselves in the art of evasion. Some in time develop specialties in criminal careers and become cunning and very skilful. In all their acts, as a rule, they show an amount of stupidity and heedlessness not ordinarily exhibited by the more professional criminals. They often possess more of the physical stigmata of degeneracy than normal persons. If anything protective or conserving is to be done with these psychopathic delinquents it must be at a very early age before the mental conflict between normal social custom and criminal acts is over. We may here cite briefly the type hastily sketched and note its manner of evolution.

CASE III is that of a girl now in late adolescence, who has always been difficult of parental management. There was a very bad heredity. Attempts to send her to school at six and eight failed as the teachers reported she would not mind or attend to her studies. She was then given private tutors whom she directed in the kind and manner of education she desired. She has remained poorly grounded in elementary education. She can or will not conform to writing and spelling correctly as it is "too much bother." She is exceedingly egotistical. She has always had sporadic but good power of mental application. Concerning practical affairs as a child she exhibited good common sense. As a young girl she was interested in the Bohemian side of life and chose to talk with boys about the rough and tumble side, prize fighting, etc. Gruesome tales were her chief delight. She voluntarily chose none of the play or work of her girl companions. She was a stoic in bearing physical suffering and often voluntarily sought and enjoyed games in which she might invite attack and physical injury (sadistic). She was easy to get acquainted with in a superficial way, but held aloof from becoming intimate. To the mother's criticism and advice she was hostile to the point of threatened violence. At ten years of age on account of her craftiness and lying she was called the "hardened little sinner" by her brothers. She considered the appellation one of honor rather than opprobrium. Although intensely impatient she never had a tantrum as a child. When jealous of her brothers and sisters she sought small ways of getting even by lying and stealing to their disadvantage. At puberty she began reading socialistic literature and espoused in a glib manner her extreme views with ideas of retaliatory revenge and torture which she would employ upon those who were in authority. All gifts of extra clothing and adornment were exchanged for money when possible. The latter she spent lavishly. She would only play games when there was a money chance. She was an adept at poker at the uncanny age of ten or eleven. Her taste in dress changed at puberty to oriental styles and colors with a lowered demand for neatness. At fourteen she was so well posted on the life of criminals and the underworld that she was nicknamed the "Police Gazette," and her sympathy was always with the criminals and their methods of beating the law. She made no attempts to "show off" as she quietly considered her innate superiority to be fully recognized. Soon after puberty she undertook writing upon psychologic subjects, a few of which were accepted for publication. At about this period (15 to 17) she appeared desperately bored with the commonplaceness of family life and began secret visits to the underworld. Apparently in these wanderings she was considered by her companions as "a peculiar kind of bug" but not without a certain genius for good comradeship. The more important events in social and political affairs of the world never concerned her. She finally fell prey to some designing persons (mostly men) who led her into all sorts of confidence schemes and thefts. Some of these, combined with sexual delinquencies, furnished intolerable episodes and caused the parents to ask for a mental examination. It revealed no special intellectual defect but marked moral obtuseness and an entirely disinterested attitude toward any better social readjustment. She said in a bored manner, "You see, I am tired to death of my family and all their class. I am a socialist and find those belonging to this group are the only really sincere people. I have long since determined to go my own way. I want to live entirely outside the class I was born in." When taxed with the thefts and social dilapidations she answered, "Oh, as to those, I was thoughtless and shall do nothing like that again. I fully intend to make my own living from now on supplemented by the small allowance from the family. Perhaps I shall write some special articles. I have lots of ideas." She seemed to have no insight as to her dilemma, and soon became suspicious and uncommuni-

cative. As her parents would not have her placed in a reformatory or have her declared a mental incompetent and delinquent, further study was impossible.

This fragmentary history is specifically given in order to illustrate the very early formation of a perverted character and faulty adjustment. Undoubtedly from six to nine years was the period of her keenest conflicts and an attempt to readjust at that time might have been undertaken with some hope of success. In this brief record one is able almost diagrammatically to forecast the next step in the evolution of such a character. Here the delinquent and antisocial aspects of the personality are overcast and shot through with a sadistic lust for cruelty and conquest. Perhaps one may say that an admixture of such an instinct really determined the specific delinquency in this girl and finally brought about her social downfall.

In many inferiors as adolescence is passed and the conduct disorders persist it has been found necessary to remove all sorts of inhibitions and prohibitions of the home environment. Many temptations of the latter have been obviated and the subject has often done surprisingly well when sent to a sanatoria school. Unfortunately such places are all too few in this country. In these sanatoria schools definite routine and principles of occupations have been put in use. It must be borne in mind, however, that the inferiors who have but a superficial insight into the nature of their disorder do poorly in this special school environment unless a certain amount of compulsion be employed. The proper tempering of this discipline is a fine adjustment of tact as yet poorly attained by the average pedagogue in charge. When one recognizes that everything depends upon the degree of insight the inferior gains into his own faults of character the kind of teaching assumes an entirely different aspect from that ordinarily, practised even in the loose association of a boys' outing school, although the latter combined with Boy Scout training more nearly approximates the method of teaching than any other. Personal talks in which the preaching attitude is eliminated is the better system to follow. The most obvious fault in the majority of inferiors is their unwillingness or inability to subscribe to and practise the usual social customs or be governed by the rules of everyday life. This being the case the subjects may be required to work together, not only to promote sociability, but a spirit of close comradeship is best promoted by such a life. Ambition is not a little stimulated by judicious practice or small rewards; but both are more frequently overdone than otherwise. Tact, friendliness, and perseverance are the main leads in the process of education. A continual influence which strongly emphasizes the mutual cooperation of the group in the same pleasures, instruction, and athletics will aid in getting the best results. The main advantage sought in such a plan is to establish a sort of free social environment to which the inferior mechanisms of the individual can adjust and get something out of.

The mistake often made with the constitutional inferior is the lack of personal enthusiasm and color in the work laid out. He should not be shielded from actual work, for considerable mental and physical restlessness is engendered if his occupation does not lead to a specific goal. As a rule all those interests that promote restlessness, day-dreaming and aimless activity are bad for the constitutional inferior. The study of music, painting, and literature are better as avocations than vocations. Almost invariably they present themselves as candidates for the stage, writers of fiction, painters, and inventors. If these desires are constant they may be treated as bona fide objectives for the time. An education in the best sense may be built around a thorough study of any one of these subjects if the constitutional inferior is properly grounded. A study of English and the classics leads to the stage; precise musical practice, the drawing of antiques, and the study of mechanics may be made to lead to their respective goals of a career in music, in painting, and invention. Concentration of attention, perseverance, and knowledge of the fundamentals are as basic to the accomplished artist as any other walks of life. Insight is not a little promoted by actual demonstrations as well as by abstract talks. Time is not really lost by any method of fair and careful test which may steadily teach the inferior his place in the world and the methods by which other more gifted persons have attained their ambitions. Unstable occupations such as salesmanship, abstract studies in philosophic and metaphysical speculations, etc., are not to be encouraged, as they fail of precise and circumscribed mental training. The sensitive and quarrelsome are often subject to revery and brooding. A concrete education along industrial lines is here of greatest value. The shiftless and spineless may be encouraged by systematic duties about the home and school, thus assuming a sense of duty and responsibility. Physical and semimilitary training, if not of too taxing a character, not only increases physical endurance but helps to fortify the will and build up habits. Comradeship with the strong always helps. Many a Steerforth of the right sort, as shown in Dickens' portrayal of this character in David Copperfield, is a real savior in the boy-world, and likewise the headmaster in the girls' school may add the materials necessary to knit together a stability in an otherwise loose clay of character.

It is quite obvious that the abnormal trends in development if not inherited begin to show themselves in the early nursery period of the home training or as soon as the child has passed into the care of the school with its broader associations and impartial discipline. Therefore, training treatment should be instituted at that time. It is obvious from the studies of such cases and from my own experience that the adaptation to social discipline comes about at an earlier period than in ordinary adolescents. It would at least seem so. It might therefore be said that the social deviation in these cases is really precocious and hence would call for extra early attention. If the evil portent of these abnormal behaviors are not on their surface detectable, or the parents are incapable of appreciating which trends in development are benign and which malignant, a campaign of general education in child-development should be given to the parents. Mental

clinics in connection with the schools should be established wherein each student might be considered as a probationary pupil. It would then be possible to detect these more malignant attitudes of conduct which later might become a serious impediment to the individual's social development. No doubt early detection and correction at the time the mental conflicts are first shown are the main leads toward proper prevention. The next step: if by precautionary and proper disciplinary measures these conduct disorders cannot be corrected, one must consider either the formation of special schools in the public school system to care for these socially unstable, or one must consider sanatoria schools which shall supply the process of teaching social adaptations while the more strictly intellectual training is being undertaken. As has been suggested, it might be possible to establish a series of ethical community groups which might be considered in the nature of schools in the larger sense where unstable individuals showing the most response to educational training could be sent until they approximated the unrestricted freedom of activities as in normal living. Those incapable of making the normal grade of social adaptation might be sent to communities with greater restrictions and less freedom, while those incapable of even this adjustment should be permanently restricted to the type of community life to which they can adjust. I believe that this latter idea is something of the purpose which the administration of the George Junior Republic have had in mind. It would not be amiss if teachers handling such classes should gain a more definite understanding of social and behavioristic psychology and have a general training in the ethics of conduct independent of a religious training in a strict sense. Undoubtedly the two factors that the more adult cases would require as a stabilizing influence are by way of religion and love. To just what extent religious institutions could be made of this larger service for this type of social misfit is still in the domain of conjecture and possible experiment. The enormous importance of a proper love-motive is undoubtedly the greatest factor to be studied and employed. Marriage, however, and the possible transmission of inferior tendencies are matters which need serious consideration. Inasmuch as anything short of complete segregation would not bar this contingency, it might be a good plan for us to consider whether marriage might not be permitted in certain instances under proper control and advisement.

It is a very nice question to decide how much this special character defect is inherited and how much really due to environment. To those possibly inclined to avoid the practical issues of more intensive training the attitude that it is an *inherited* defect probably would appeal most; to those who maintain that improper training really plays *the* important rôle it is possible to take a less pessimistic view so far as prophylaxis is concerned. Whichever viewpoint is taken, however, as good mental hygienists we cannot escape the issue of doing what we can with such modifiable factors with which we have to deal. A campaign to educate the lay public, educational authorities, and especially those interested in children's courts, needs to be seriously considered as a great help to solving our problem. Everyone having to deal with the courts, and especially those courts controlling person and estate, knows how difficult it is to explain to judge and jury the nature of these social defects. They customarily hold a very wide latitude of social prerogatives for most persons in everyday life. Unless the social delinquencies are very glaring they are unwilling to take precise action to materially help in our problem.

What attitude should society in general take toward the socially unstable as outlined in the case studies of this paper? Obviously it should first be individualistic. Case I needs to be supervised to such an extent that an unsuspecting public may be safeguarded from depredation of property interest (stealing, etc.); secondly, many such may lead immoral lives if the means of the parents fail and they are forced to make their way in the world. To a certain degree the same may be said of Case II. The latter is younger and may be induced by proper training to observe more or less strictly the conventional customs of society. But as to Case III, in whom definite and fixed mental attitude toward society seems to have been already taken, society there demands specific protection by segregation. Undoubtedly here the aggressive and malignant instincts were almost predetermined from the outset. A few traces of possibilities of reclamation were manifest at six to eight years of age, but these may have been too slight for conserving a character so inherently defective at birth.

From the parents' standpoint all these cases have been and must continue to be the source of keenest social anxiety. Nothing less than segregation or safe policing would bring any comfort to anxious parents. From the socially unstable's standpoint a flexible training system, moral and ethical, would meet the situation with comfort and possible happiness. Can all these three demands, of society, the parents, and the unstables themselves, be met outside an institution? It may be tried, and often is. Success in such extramural training is perhaps too little reported and hence the specialist has grown to take too gloomy a view of the chance of such a procedure. I am inclined to think so; just as the psychologist and psychiatric are apt to think their particular mental tests are acid-proof of the inability of the feebleminded and morons to live in the outside world. Often such an opinion is foiled by the fact that they do, and do so nearly as well as many so-called normals. The life reaction tests are so very much more safe and vital to a final prognosis than any laboratory guide. Nevertheless the small percentage of the sum total of morons and socially unstable who may more or less precariously live in the average community life does not affect the issue for the socially unstable as a class, who after a trial of extramural corrections are only too often found incapable of safe or satisfactory social adjustment. It is just at this point that the whole problem is uncovered. Mental hospitals, private sanatoria and schools

cannot or will not take these unstables as patients or pupils. Most often the lack of certification and their nonconsent to voluntary deprivation of liberty renders their proper training and discipline impossible. In the ordinary sense they are not ill as are præcox and manic depressants; they require an entirely different system of care. Their needs are more nearly allied to those of the feeble-minded, but here again the intellectual and habit training is quite different. Their greatest need is character-building, and that, too, along the lines laid down in the main body of this paper. Practically no such institutions exist that provide the proper community environment and ethical training combined with the amount of restriction suited to the individual need. It is one of the greatest demands of our time, and such an institution must, necessarily, possess many facilities costly to maintain. While trained psychiatrists should be at the head of such an institution, it must embrace teachers and trainers in all lines of human activities and interests. Its morals should be high and worthy of the fullest acceptance and cooperation of the public and the interested relatives. To be really effective it should be under a large endowment and supervised by the State or some properly constituted authority. Until such an institution is established the great problem of care, training, and protection of the socially unstable will not be adequately met.

20 West Forty-eighth Street.

THE DIET AND HEALTH;*

AMOUNT AND KIND OF FOOD REQUIRED.

By JOHN AULDE, M.D.,

PHILADELPHIA, PA.

IN a previous paper, attention has been directed to the value and importance of a more widespread diffusion of reliable information relating to the fundamental principles underlying nutrition—the most obvious reason being the enormous quantities of food and drink annually consumed by adults, about 2,500 pounds, or eighteen times the weight of a man weighing 140 pounds. It was pointed out also, that the nutritive value of the various food materials, with the exception of vitamines, could be determined with mathematical precision, notwithstanding the fact that digestion and assimilation are rather occult problems for the uninitiated.

Special attention was directed to certain essential factors to be considered in regulating the dietary, such as age, occupation, climate, and season of the year—also the value of milk in rounding out the diet at all ages. Failure of the Army Ration system to supply a "balanced ration" was commented upon, particularly in the failure to furnish an adequate supply of sweets, such as sugar and molasses. Thus, the garrison ration provided a pound and a quarter of meat daily and less than a quarter of a pound of sugar and syrup—to be exact, 3.52 ounces—but through "trades" with the quartermaster, the amount consumed was 4.11 ounces.

With a view to present the latest reliable data relative to the "accessory food" factors, known as vitamines, in a careful summary, McCollum's experimental investigations were analyzed in order to bring out the actual facts as to the deficiencies in the various grains (seeds), as well as the predominating influence upon nutrition exercised by foods derived from the leaf. For example, McCollum asserts that milk and certain other animal foods containing the fat-soluble vitamine, together with the vegetable foods containing the water-soluble vitamine, especially the leaf, should be classed as "protective foods."

While the records are intensely interesting and informative, there is a notable hiatus or lacuna in the series, indicated by the following quotation: "Another series of rats had a more liberal diet, at least in respect to variety, namely, corn, millet seed, oats, wheat, and hemp seed, equal parts of each, but gained in weight in the course of three and a half months less than one-eighth of an ounce. On the addition of mineral salts normal growth set in at once—and it should be added that 40 per cent. of the salts were calcium, or lime."

This result led the writer to remark, "And the most instructive feature, aside from the function of the fat-soluble and water-soluble accessory factors, now called vitamines, is the "stimulating" effect of the mineral salts upon growth and reproduction."

Since this article was finished, a new and altogether unexpected complication has appeared—like the aurora borealis—upon the medical horizon; it is nothing less than the proposal of an artificially prepared stable vitamine product, together with a demonstration of its value in nutrition. The communication (*American Journal of the Medical Sciences*, Feb., 1920, p. 264), by Drs. H. E. Dubin and M. J. Lewi, gives the plan of experiment, history of the patients treated, and an interesting discussion of the results, together with a summary. Elaborate tabulations are included, also graphic charts, to illustrate growth following administration of this "stable" vitamine product. Of the 13 cases reported, only 3 were over one year, the exceptions being 19, 14, and 18.3 months, and usually, one gram of the vitamine preparation was fed daily. No less than 42 references are appended, which would indicate unflagging industry, but no one with a fairly normal conception of the catalytic properties of calcium would be misled to believe that the new compound, or combination, would produce results in a degree superior to the single elementary substance. Still, it provides a very good substitute, notwithstanding its manifest superserviceability.

Here is the formula: "Analysis shows the chief components to be calcium, expressed as calcium oxide, 10 per cent.; phosphorus, 15 per cent.; nitrogen, 3.5 per cent.; fat, 2.5 per cent.; iron, 0.3 per cent.; silicates, 5.6 per cent.; moisture, 10 per cent. The remainder goes to make up the rest of the phytin molecule—the main constituent of the product—which is a double calcium and magnesium compound of inosite phosphoric acid."

The dosage of one gram daily for a child under one year supplies 1.5 grains of calcium, so there is no danger from calcium starvation, and other dietary factors being equal, there should be no retardation in growth. In fact, the writer has frequently

*Second Paper. See MEDICAL RECORD, June 5, 1920, p. 947.

witnessed most remarkable evidences of improvement in children from the administration of one-half grain of calcium three times a day, in the form of a normal trituration, equal parts of the crude drug and sugar of milk. My impression is that, when given in this form, we secure the catalytic effects in a marked degree, and incidentally its reconstructive value is worthy of mention.

The modern science of nutrition aims to establish basic principles in order that they may find practical application in the treatment of disease, since the most valuable classification of disease is that based upon food disturbances. The evidence so far presented is conclusive, but unfortunately the experiments were mostly confined to animals, dogs, guinea pigs, rats, poultry, and pigeons, and it will be claimed that these investigations do not apply to humans; but this objection is not well taken because of the overwhelming testimony of all progressive physicians that many of the well known and common diseases are traceable directly to some deficiency or fault in the dietary. Among the most prominent may be mentioned pellagra, scurvy, beriberi (polyneuritis), rheumatism, and rickets. There should also be included in this category, nervous disorders, heart and kidney diseases, and skin affections, because they all hark back to derangements of the digestion resulting from an inadequate supply of rebuilding or reconstructive material, together with the recently discovered accessory food factors known as vitamines. So-called "general debility," which includes a vast multitude of valetudinarians, is merely a euphonious term to cover chronic starvation.

The following abstract of a paper contributed to the London *Lancet* (Dec. 7, 1918) by Dr. M. Mellanby, entitled, "Influence of Diet on Teeth Formation," is worthy of special attention, since it duplicates a defect which is almost universal in this country—and it also throws a strong sidelight upon the function of calcium as a reconstructive.

The investigation was taken up with two objects in view:

(1) The factors involved in the development of sound teeth, and of the growth of the jaws in relation to the size of the teeth; and (2) The factors bearing on the immunity of erupted teeth to caries and other diseases.

The author discovered that failure in growth of the teeth is caused largely by a deficient diet, and that the factor in the diet which controls the calcification of the teeth is something in the nature of an accessory food factor (vitamine). A diet containing an abundance of those articles with which the fat-soluble vitamine is associated, such as cod-liver oil, butter, etc., allows the development in puppies of sound teeth. A diet otherwise adequate, but deficient in the substances with which the fat-soluble vitamine is associated, brings about the following defects:

(*a*) Delayed loss of deciduous teeth; (*b*) Delayed eruption of the permanent dentition—in some cases the delay in the eruption of the permanent teeth is more marked than the delay in the loss of the deciduous teeth; (*c*) Irregularity in position and overlapping, especially of the incisors; (*d*) Partial absence of, or very defective enamel; (*e*) Low calcium content. The deficiency in calcium salts may result in the teeth being so soft that they can be cut with a scalpel.

With this evidence in view, those argumentative partisans who claim that early tooth decay is due to sloppy food and lack of sanitary and hygienic measures will have to furnish up their armamentarium, or take a rear seat in the procession.

It should be mentioned here that this experiment rather upsets the theory so strongly urged by McCollum that the absence of fat-soluble vitamine from the dietary leads to inflammation of the eyes and blindness (xerophthalmia), and at the same time creates an incentive to learn something more definite regarding the real function of the calcium salts in promoting normal growth. Let us recall the properties of calcium—antacid, catalytic, and reconstructive. Is it not possible that it may be employed medicinally as a chemical food? And this supposition is warranted, being frequently verified in the practice of every physician in treating the disorders of infancy and adolescence. It has already been noted in several experiments in which the addition of mineral salts to the dietary lacking the fat-soluble vitamine showed immediate response and rapid growth followed.

The employment of calcium or lime salts in the treatment of disease is rather antiquated and regarded as empirical, but it is none the less efficient—and is destined to arrive in time. In the case of inventions as well as discoveries, there comes a time when the promoter or reformer is "up against it," but time works wondrous changes. Hindsight is so clear and comprehensive that solution of the occult problem appears as merely a natural sequence. The following quotation from an elaborate paper on "Fat Soluble Vitamines" (*Journal A.M.A.*, Jan. 24, 1920), by Drs. Hess and Unger, furnishes an apt illustration of this suggestion. In this instance, the failure was due to a slight oversight—non-recognition of the fact that calcium is an essential food material, and also the possibility that although present in the milk and other food it may not be available, owing to some chemical or physiological deviation from normal. In such cases modern science demands its medicinal employment. Here follows the extract:

"In order to provide an adequate amount of this important dietetic factor, we placed a number of infants, during the first months of their lives, on large amounts of milk, in some instances giving cream in addition. By this means, if fat-soluble vitamine is the controlling influence, the development of rickets should have been prevented. In some cases, with this dietary, which it will be remembered included also orange juice, a very mild degree of rickets was observed, but in others marked signs developed."

While animal experiment cannot be reproduced in man, nor reliable data secured even from many individual tests and complete records, owing to varying ages, dietary habits, season of the year, and occupation, it has been possible to secure definite information regarding *results attending prolonged reduction of the diet.* This study, which was taken up by Dr. Francis G. Benedict, of the Carnegie Nutrition Laboratory, Boston, Mass., shortly after the United States entered the late war, presents an array of facts which are both suggestive and illum-

inating—and besides, they are accurate and dependable. The complete report of this experimental work has been published in book form and embraces over 700 pages, so we can only present here the conditions imposed, together with a brief summary of the most vital conclusions—in respect to a reduced diet. It is stated, "The effects on the various functions were striking."

"For subjects we selected 12 young men from a considerable number of volunteers from the student body. . . . The average age of the men was 23 years. For a period of four months these men were kept upon a much restricted diet, with an energy content approximately one-half or two-thirds their caloric requirements prior to the test. During the first few weeks there was a distinct drop in the body weight. When the body weight had fallen on the average 12 per cent. the calories in the diet were increased so as to prevent further loss in weight. The measurement of the caloric consumption at this sustained weight level would indicate the true caloric required for maintenance. For control, 12 men from the same student body, living under exactly the same conditions, save for the dietetic restrictions, were likewise studied and their food intake occasionally measured for periods of four or five days." Here follow the conclusions:

"1. The reduction in weight was effected by reducing the caloric value of the food from 3,200 to 3,600 calories, a moderate amount of protein being allowed. One squad of men subsisted for three weeks on 1400 net calories without special disturbance.

"2. After the loss in weight of 12 per cent. had been reached, the net calories required to maintain this weight averaged about 1950, or but a little more than one-half of the original amount required —supplied.

"3. At the end of the reduction in weight the actual heat output during sleep was about one-fourth less than normal. There was no seasonal variation in metabolism (nutritive changes), as compared with the metabolism of the control squad.

"4. The heat output was essentially 18 per cent. lower than at the beginning of the study.

"5. Analyses of food, feces and urine showed a marked loss of nitrogen during the reduction period and for some time afterward, a loss which 'we believe distinctly lowers the stimulus to cellular activity.'

"6. The nitrogen output per day was about 10.5 grams, while that of the control squad showed a nitrogen output of 14 grams per day.

"7. The pulse-rate was astonishingly lowered. Many of the men showed morning pulse-rates as low as 33, and daily counts of 32, 31 and 30 were obtained; at least one subject gave six definite counts on one morning of 29.

"8. The blood pressure was distincly lowered. The skin temperature, as measured on the surface of the hands and forehead, was, in some subjects, considerably lower than normal, although in most cases normal temperature prevailed, and the rectal temperature was practically normal.

"The general picture that the men presented at the end of the test, or at their minimum weight, was one of noticeable emaciation, particularly in the face, but all the men continued the usual college activities with no obvious reduction in stamina. . . . The most notable discomfort experienced by the subjects was a feeling of cold. . . . The whole period of lowered food intake had no untoward effect upon the physical or mental activities of these men, and they were able to continue successfully their college duties."

Referring to Dr. Benedict's investigations and the results, and comparing them with similar observations by the German physiologists, Zuntz and Loewy, extending over a period of several years, an editorial writer (*Journal A. M. A.*, Feb. 22, 1919) makes the following pertinent remarks to show that "the laws of the conservation of energy are immutable":

"Although it is evidently possible to keep alive through reduction of weight to a figure at which smaller maintenance rations suffice, the experience of Zuntz and Loewy during periods of work carries a sinister warning. They found that the expenditure of energy in an active effort at marching was decidedly larger than had been observed in earlier days when they were more adequately nourished. The increased consumption of oxygen, both during the period of exercise and in the stage of recuperation immediately following, was sufficiently striking to indicate the unfavorable effect of under-nutrition on muscular performance. The consequence deserves to be prominently noted, because many of the studies on restricted feeding have been concerned with the problem of maintenance alone without due regard to the economy and ease of work under the conditions investigated. The factor of safety may withstand the depreciating effect of a few days, or even weeks; but months of enforced economy are likely to bring it nearer to the vanishing point, where even moderate effort begins to involve a severe sacrifice."

This ex-cathedra decision is countered by the evidence, or information, elicited from the Laboratory for Nutrition Research, Copenhagen, Denmark. Dr. M. Hindhede, referring to the war blockade, says (*Journal A. M. A.*, Feb. 7, 1920: "Reliance was placed on our potatoes and large barley crop, which was given to man and not to the pigs, as heretofore, with the result that the pigs died of starvation, but the people received sufficient nutrition. . . . Our principal foods were bran bread, barley porridge, potatoes, greens, milk, and some butter. . . . It is evident, therefore, that most of the population was living on a milk and vegetable diet."

As a result of the food restrictions during one year of "severe regulation," the death rate, as compared with the preceding ten years, was reduced over one-third—34 per cent. In view of the fact that the Government took the cereals and potatoes from the distillers so that they could not make brandy, and one-half of the cereals from the brewers so that the beer output was reduced one-half, the author asks this question: "Is it possible that this reduction in the output of alcoholic beverages is wholly responsible for the lower death rate?" This question, he says, cannot be answered, but he is willing to admit that it is a great contributing factor, although not the only one, because the death rate among women had decreased 17 per cent. during the four preceding years, and it is unlikely that

alcoholic abstention was a factor in producing this marked reduction.

In conclusion it may be said that even a casual examination of the foregoing observations supplies a convincing proof of the fundamental importance of the dietary, and at the same time develops the common or usual signs and symptoms incident to impairment in nutrition—all the talk about fresh air, sanitation, and environment to the contrary notwithstanding. Certain disorders have been traced directly to this cause, and it is but a question of time when others must fall into the same category—it is not likely that we shall much longer be able to cover chronic starvation by the euphonious term, "general debility."

Special attention is directed to the effect upon tooth formation, owing to the lack of fat-soluble vitamine as well as the lack of lime salts in the dietary, and the probabilities are strong that both are essential. This is well shown in the case of rickets, reported by Drs. Hess and Unger, where an ample supply of the fat-soluble vitamine failed to prevent the development of rickets, even with the addition of orange juice.

Prolonged reduction of the diet (in men), as demonstrated by the indefatigable labors of Benedict and his associates, *seems* to cap the climax in the "striking effects" resulting from under-nutrition, but we must correlate these results with the elaborate experimental investigations of Osborne and Mendel relative to the nutritive properties of certain amino-acids. Such studies will shed a flood of light upon the cause and the conditions leading to illness, and especially to the instances where the attacks are sudden and wholly unexpected—with a fatal termination. Thus, young animals subsisting upon certain pure proteins will make no perceptible gain in weight for weeks at a time; upon the addition of lysin, the amino-acid widely distributed in both animal and plant life, they take on growth at once, coming to a standstill again when lysin is discontinued.

The report of Hindhede, of Copenhagen, showing how the Danish people, during the war, saved their own lives and reduced the death rate over one-third, by eating the barley and potatoes themselves and letting the pigs die of starvation, is suggestive. The fact that the Government commandeered a large part of the cereals and potatoes, lessening the manufacture and sale of whiskey and beer, may have had something to do with the reduction in the mortuary statistics, but that is a question to be settled by the statisticians.

1024 WALNUT STREET.

HEADACHE FROM THE STANDPOINT OF THE OPHTHALMOLOGIST AND OTO-LARYNGOLOGIST.*

BY ELBYRNE G. GILL, M.D.,

ROANOKE, VA.

IN bringing the above subject, which has been discussed so extensively, to the attention of this large and experienced audience, it is not so much the desire of the writer to present his own observations as to elicit a full discussion by the members of all branches of the profession who have to treat this most frequent, most trying, and often times most confusing of all symptoms.

While medical science, in its rapid and magical strides, has in the past decade found cures for many deadly maladies, we find with us yet a "symptom" of a disease which often causes the patient more actual discomfort, pain and suffering, and the physician greater anxiety while trying to relieve it, than a real disease. This is headache.

From the subject of my paper you would judge that I am to discuss this subject only from the standpoint of my specialty, and in order to do this intelligently, it will necessarily require an enumeration of all conditions known to the human mind which are capable of producing this symptom, and then, by a careful and painstaking process of elimination, in most instances you will find the seat of your patient's trouble.

In this process of elimination, you necessarily have to summon to your aid the counsel of your colleagues, namely the internist, the X-ray specialist, the laboratory expert, the neurologist, etc., for not infrequently the underlying cause of this symptom is found in organs remote from the head. He who would render the greatest service to the half indifferent sufferer with an occasional headache, or to the despondent victim who has made the rounds of the various specialists in a vain search for relief from a torturing, persistent headache, must seek to trace the symptom from the seat of pain through intricate labyrinths of possible causes to the ultimate real cause. In all the category of symptoms no other, perhaps, owes its origin to such a wide field of different, varied, diversified causes; therefore, he who would successfully locate the cause of headaches should take a broad, comprehensive view of the entire field, for in this day of specialization we are prone to look through a lens, thus magnifying the defect that lies in our own territory.

As an example we might have a case of choked disc and an involvement of the accessory sinuses. Should we be satisfied with our examination of the patient? No! Our examination should embrace the entire field which would necessarily include a Wassermann blood test. The writer recently had a case of double choked disc, also an involvement of accessory sinuses. Did the examination stop? A Wassermann was taken and it proved to be 4 plus. Under anti-syphilitic treatment the patient's condition showed marked improvement.

Classification.—A classification of headaches is difficult because the theories as to the cause of this symptom are so much at variance. It has been my pleasure during the past few weeks to review the literature on the subject of headaches. During the past ten years approximately 200 articles have been published on this subject. It is quite interesting to note that every writer has theories as to the cause of headache and advances numerous arguments to sustain his hypothesis. From a clinical standpoint headaches may be divided into 1, the persistent headache; 2, the periodically recurring headache; 3, the occasional headache. From an etiological standpoint headaches may be classified

*Read by title at the annual meeting of the Tri-State Medical Society, in Charlotte, N. C., February 18, 1920.

as follows: 1, toxemic; 2, neuropathic; 3, reflex; 4, circulatory. Under *toxemic* we place 1, retained products resulting from defective metabolism; 2, infectious microorganisms or their toxines; 3, various drugs; 4, Graves' disease. Under *neuropathic*, 1, neuresthenia; 2, hysteria; 3, epilepsy. Under *reflex*, 1, ocular; 2 basopharyngeal; 3, auditory; 4, dental (impacted teeth); 5, gastric; 6, pelvic. Under *circulatory*, 1, hyperemia; 2 anemia.

Method of procedure in examining the patient who comes with headache as the chief complaint.— First and always take a careful and complete history of the case. In searching for the cause of a headache the diagnostician should view from an eminence not only the many fields in a patient's own domain, but also his environments, and even looking beyond these into the realms of his ancestors. Having obtained a careful history, we proceed with our examination. The nose is carefully examined as to the appearance of the membranes, evidence of secretions of any character, points of contact or pressure, deviations of the septum, etc. Intranasal pressure as a causative factor in producing headaches is well known even to the most superficial observer. In case pathological changes are found within the nose the examination is continued until every remaining possible cause has been carefully considered and eliminated as far as possible. The nasopharynx, the oropharynx and the laryngopharynx are given the same careful examination. The sinuses are transilluminated, and if doubt exist in regard to the condition of any one sinus the *x*-ray specialist is consulted. The eyes are examined externally, intraocularly, as to refractive error and muscle balance.

The question now arises as to the differentiation between ocular and accessory sinus and intranasal headache. This is sometimes difficult as each one may have a part in producing the symptom. One patient will complain of inability to use his eyes for reading, say for the past two weeks, without severe headache; another states that he has an intense headache in the morning on awakening, cannot bear the light, the ache wears off by noon; a third has neuralgia over one eye. Are these headaches of ocular, sinus or what origin?

It is usual for the practitioner first to consider an ache in the head as dependent upon a disordered condition of some other part and then, failing of cure, to have the head examined by a specialist. Had the patient been examined from every angle at first how much suffering would have been spared.

In a short paper, such as this must be, it will of course be impossible to take up even briefly the various forms of eye strain. Volumes have been written upon the surprising and far-reaching effects upon the whole body, and especially upon the nervous system, of ocular reflex neuroses. This much is certain; no examination is complete without a careful estimate of the refraction and muscle balance.

Differential diagnosis cannot always be made by following any given table or set of symptoms, as every case is a law unto itself. The history of the case, the time of appearance of headache, the duration, and the findings on examination of nose and accessory sinuses, will usually reveal the offending organ.

Having examined carefully the eyes, ears, nose, and throat, we proceed further regardless of the presence or absence of pathology, by recording the blood pressure, having a complete analysis of the urine, and in every instance of an obscure headache a blood Wassermann. In case all of our tests have proven to be negative our patient is then sent to the internist. We collect the reports of the *x*-ray and laboratory expert and internist, and with our findings we study the facts carefully and then proceed to correct any existing disorder, starting with the most formidable one first.

While discussing the method of procedure in carrying out an examination, we feel that a word should be said in regard to the prescribing of glasses for the relief of headache without making a further effort to find the cause of the trouble. We do not think that an ophthalmologist is ever justified in prescribing glasses for relief of headache without first having obtained the otolaryngologist's report and a complete uranalysis, and in every instance in an adult a blood pressure reading, and, even better still, a blood Wassermann report. We base the above statement upon the firm belief that a man is no more proficient as an ophthalmologist or otolaryngologist than as in internist.

The importance of having a blood Wassermann made before prescribing glasses is clearly set forth by the following case which came under the observation of my former associate. A boy, age fourteen, was sent in by the school nurse on account of defective vision. At that time the left eye showed a slight conjunctival injection. The boy was refracted under a mydriatic and glasses were given. About three weeks later he came in with a marked inflammation of the left eye and a beginning keratitis. A Wassermann was then taken, which proved to be 4 plus. In spite of active antisyphilitic treatment the boy, after five months, still has his keratitis. It is easy to say what would have happened if we had done this or that at first, but it is evident to all that this boy would have been saved the expense of buying glasses and possibly would have been spared the unfortunate eye condition which he now has, had he been given antisyphilitic treatment three weeks sooner.

My work is confined strictly to otolaryngology, consequently I can judge the results obtained by the correction of errors of vision for the relief of headache only by the work of those practising ophthalmology, and it has been very unsatisfactory in many instances. In this connection it has been interesting to note the results of an examination of one hundred patients in an asylum for the blind which showed thirty-four who were sufferers from headache. These patients were blind from birth. It would be still more interesting, if it were possible to know how many of these sufferers would be wearing glasses, or rather, would have been given glasses to wear, had they been fortunate enough to have been born with good eyes.

We do not wish for any one to assume that errors of refraction do not produce headache, but our aim is to impress upon the eye man the importance of always making a thorough examination of all possible causes so as to support what he has done by correcting the visual error.

Before leaving the subject of examination of the patient we feel that something should be said of a disharmony of the glands of internal secretions as an etiological factor in the production of headache. The gland which has of late been known to cause headache is the pituitary. Thirty years ago the pituitary was considered a rudimentary organ, a vestige, a non-functioning cerebral appendix. In 1889 Marie associated an enlarged hypophysis with acromegaly. Howell, in 1898, extracted an active secretion from the posterior part of the gland. Harvey Cushing, in 1910, produced his epochal study on the pituitary, which gave us the modern conception of the physiology and clinical manifestation, and it was he who first coined the term dyspituitarism to cover those conditions due to a perverted hypophyseal secretion.

Pardee, of the New York Neurological Institute, in the *Archives of Internal Medicine*, February, 1919, has a very interesting and illuminating article on pituitary headaches and their cure. He reports seven cases of headaches of pituitary origin which were relieved by the administration of whole gland pituitary extract. His conclusions are as follows: "1. Pituitary disturbances constitute a fairly common cause of headache; 2. Pituitary headache is located between the temples, deep in behind the eyes and is accompanied by dyspituitary signs; 3. Abnormality of the sella turcia is demonstrable in almost every case of pituitary disease; 4. Administration of the whole gland cures these headaches and the accompanying symptoms in a large percentage of cases, provided there is not a progressive neoplastic growth."

So much has been written and so much has been said about headaches resulting from eye strain, ear, nose and throat disorders, gastrointestinal disorders, cardiovascular and cardiorenal disorders that mere narration of additional cases will be of no avail. We wish to report two cases of unusual interest:

CASE I.—Patient, W. B. H., male, age forty-one, came under observation January 13, 1920, with the following history: Patient has suffered with headaches at times since childhood. For past seven months head has ached almost constantly. Dull pain in the temporo-occipital region. General health good. Married. Three children living; wife had no miscarriages. Special examination: Slight deflection of septum to the left, mucous membranes normal in appearance. No evidence of pus. Sinuses O. K. Tonsils removed clearly two years ago. Ears O. K.. Eyes, V. O. U. 20/20; O. D., 20/20; O. S., 20/20. Has two pairs of glasses, sees better without the glasses. Blood pressure, S. 120, D. 80. Urine negative. Wassermann negative.

In view of our negative findings and the fact that the patient had been through the hands of a number of competent internists with negative findings and with the history of headache since childhood, with some of the symptoms of dyspituitarism, we felt that the headaches were of pituitary origin. So, acting upon that theory we sent the patient to the *x*-ray specialist for a roentgenogram of the sella turcica. The following is the report: "Stereoscopic *x*-ray of patient W. B. H. shows marked enlargement of anterior and posterior clinoid processes, the distance between the tips of the anterior and posterior processes being not more than one-eighth of an inch, the normal being not less than one-fourth of an inch. The effect of the evident approximations of the tips of the processes and enlargement is a constriction or pressure on the pituitary gland itself. There is as yet no erosion of the process."

The patient was placed on pituitary extract, Whole Gland, grains one and one-half three times a day. After the end of one week the patient felt some better. The dose was increased to three grains three times a day and in a few days following, the patient contracted influenza and has not been seen since. The slight improvement obtained after the first week's treatment makes us feel that we are on the right track.

CASE II.—Patient, W. M., male, age forty, was seen in consultation with Dr. G. M. Maxwell, January 17, 1920. Patient's family doctor gave the following history: Patient married, seven children living and well. Has had headache at times for past five or six years. During the past three months has been nervous and has had a left frontal headache almost constantly. On January 15 patient walked five miles to see his family physician. His physician told him he would have to be sent to a specialist in Roanoke. Before the patient could arrange to leave he suddenly became unconscious and his heart became irregular and very slow. In a few hours the patient's condition became more favorable and the following day he was brought by train to Roanoke. The examination revealed the following: Eye grounds, nose, throat and ears negative; sinuses O. K.; urinalysis negative; blood pressure normal. Mentally the patient was suffering from word aphasia. For instance, when shown a knife he could not name it but would say you cut with it. Blood Wassermann 1 plus; spinal fluid Wassermann 4 plus. The chief point of interest in this case: A man forty years of age, farmer who does manual labor every day, has seven healthy children, wife never had a miscarriage. It served the importance of making every possible examination in order to locate the cause of an obscure headache, regardless of the past history.

In conclusion, we feel the necessity of impressing upon the minds of the men in all branches of the profession the importance of considering the symptom headache as nature's call for help, which should be heeded while the disease is amenable to treatment. At times we are confronted with a headache which is the only symptom, or at least the only conspicuous symptom, of some grave disease, which, if this danger signal be ignored, may seal the patient's doom before the other symptoms attract attention. Headache may be only apparent manifestation of a brain tumor, meningitis, typhoid fever, small-pox, acute nephritis, etc. The physician should always be on his guard.

Even if headache did not sometimes give warning of the presence of a deady foe it would nevertheless demand most careful consideration because of the fact that it affects the comfort of more people, perhaps, than any other ailment, often incapacitating them for the highest enjoyment and the brightest achievement, often rendering existence itself almost intolerable.

Diabetes a Defense Reaction.—Leclerq states that during the fifties we suffer especially from maladies of nutrition which are in reality all defense reactions. Diabetes is due not to abuse of starches, but abuse of nitrogen. Diabetes is not a disease, but a defense reaction against food poisoning of exogenous or endogenous origin. In this affection the mechanism for disposal of these poisons breaks down. During the progress of the process the offending bodies are oxidized as far as sugar, and other diseases like arteriosclerosis, which result from nondestruction of toxic material, are prevented. If the malady is rationally managed the sugar should disappear from the blood.—*Le Progrès Médical.*

PARALYSIS AGITANS AND SYPHILIS.

By BERNARD OETTINGER, M.D.,

LONG BEACH, CAL.

In the course of routine physical examinations, I noted in four consecutive cases of paralysis agitans certain large deep scars involving the corium. The scars were multiple in each instance, regularly round or elliptical, with edges plainly marked about the entire periphery. Although a number were about the knees, others were in the skin overlying soft tissues, little exposed to trauma. Previous infection of confluent smallpox, tropical sores, skin ulceration following the use of the hypodermic needle were excluded. Likewise was ruled out the more superficial scarring at times seen in a patient who at some previous time has had an eczema with secondary skin infection, and also the small deep pockmarks that are relics of varicella. In the next succeeding case of Parkinson's disease (a physician) I found no depressed cicatrices but noted one scar near the right scapula and two in the small of the back, each slightly larger than a kidney bean and something of this shape and all showing evidence of connective tissue overgrowth. I said to the patient, "I note some scars not of the usual type but the like of which I have heretofore seen in persons who have had syphilis." He answerd "I have had syphilis and have taken treatment for it. A Wassermann test has been made of my blood. It is negative." Of the five cases four were men and one a woman. Salient data of the five cases were as follows:

Case I.—A man aged 55 yrs. One child and living; "touch of typhoid at 20" but kept on his feet. Two years ago felt numb on the left side for six months; "something felt coursing up the left arm and into the back." The left arm externally, above the elbow, and the right externally, below the elbow, is sore to touch. Tremor and stiffness developed gradually, the latter predominating.

Case II.—Man aged 65 yrs. A glycosuria which the patient knows has been present many years. History of soft chancre and phimosis 10 years previously. Both patellar reflexes absent even on reinforcement. Romberg present. Complains of pains in the head, in the left shoulder and arm and both legs. He says all pain and rapidly developing tremor occurred as a sequence of a train wreck which he was in a month previously. Some nonpitting edema about and above the ankles. Blood Wassermann negative.

Case III.—Man aged 53 yrs. An early case developing gradually in which stiffness is the predominating symptom. Was badly burned 20 years previously by a high voltage current. A very reticent patient. Sexual impotence. This fact stated by the wife and not denied by the patient. An otherwise negative history.

Case IV.—Man aged 50 yrs. Pronounced coarse tremor which developed after an operation in the ear. Little stiffness. Lues admitted. Blood Wassermann negative.

Case V.—Woman aged 60 yrs. Twice married; no pregnancies. Occasional pain in the pit of the stomach, frequent nausea. Has had sciatica. A year ago pain and swelling in both knee joints. One notes a coarse tremor which is almost a twitching mainly about the head and neck. For the same reason the patient is not able to chew her food well and infrequently chokes when swallowing. Enunciation is jerky.

The above concludes observations as to five private cases who presented cutaneous scars.

Subsequently I was given the opportunity to examine seven cases of paralysis agitans at the Los Angeles County Hospital. All of these patients presented advanced cases of the disease. As a result, difficulty of obtaining a case history was experienced on account of speech involvement up to complete inarticulation, while memory loss due to senile changes effected the same result. Again, the frequently encountered great muscular rigidity and pain interfered not a little with a good physical examination. Nevertheless, a report of these cases is utilized for the reason that although Parkinson's disease is not extremely rare, it is yet sufficiently uncommon to prevent individual practice offering records of many early cases unless observations are carried on over a considerable number of years.

Case VI.—Man aged 45 yrs. History of a soft chancre. On the right leg anteriorly, two large, round deeply pitted scars; on left leg anteriorly one, and posteriorly two scars of the same character. Blood Wassermann negative.

Case VII.—Man aged 67 yrs. Has on both legs a number of large circular, pigmented scars involving the corium. The hospital history taken some years previously states "probably had lues 42 years ago." I do not not know the basis for this statement. Speech is much involved. One delves into the clinical history only with the greatest difficulty but I make out that he denies any venereal infection.

Case VIII.—Man aged 45 yrs. Coarse tremor of all extremities but intelligence is good and speech plain. A number of very small circular superficial scars are noted on the limbs and flanks. Because some of the scars show an edge for only a part of a circle, these appear cresentic. Such cicatrices are often seen in persons presenting also the large deep scars of healed syphilides. While unable to regard them characteristic of lues, they are quite unlike the small pitted area of chickenpox or the irregularly outlined scar of trauma. This patient's skin was otherwise clear. However, he gives a history of a penal sore in 1911 followed by sore throat and a rash that extended over the whole body. Feeling physically unfit, he consulted a physician in Santa Rosa, Calif. After a blood test the patient was told his blood was "bad." A year later finds him in the Denver County Hospital. Here a spinal fluid test was made the result of which was "positive." He was then given an intraspinal injection. The chart shows that a blood test made in the Los Angeles County Hospital finds the blood negative, but because the patient has much pain in his limbs which is relieved by arsphenamin, he has so far received three intravenous injections of this drug.

Case IX.—Man aged 45 yrs., the disease far advanced, of twelve years' duration. Mask like facies; great muscular rigidity; practically inarticulate. Involuntary bowel movements. Examination of the skin surface shows a number of small scars similar to those referred to in the previous case but in addition on the inner side of the left thigh is a ham colored indolent ulcer already involving the corium. Its thin basal cutaneous surface is crinkled. The ulcer is no larger than a pea but apparently is a typical syphilide. Blood Wassermann negative.

Three women patients, all very advanced cases and inadequately examined because dressed and in wheel chairs, gave different results. Speech involvement and impaired mentality precluded satisfactory histories, nor did the clinical charts reveal anything of moment. One patient showed a few indeterminate looking scars and had lost three or four children in early infancy; one patient presented a double Babinski and involuntary action of bowel and bladder. Two of the women showed a negative Wassermann. As to the third patient, this test had not yet been made.

The facts recorded concerning the last three cases accentuate what has been said of the desirability of containing a history during such early period

of the disease as to yield an anamnesis. But as the record stands, in nine of twelve consecutive cases of Parkinson's disease evidence that ranges from reasonably presumptive to certain that a sometime luetic infection occurred, presents a sufficiently high percentage to be notable, and so, probably merits further observations along the line indicated. Interesting is the fact, that the blood Wassermann was negative in every case tested including those instances whose history disclosed certain syphilitic infection and the further fact that one of these had previously given a positive blood and spinal reaction. Again, barring one case presenting a complex symptomatology, namely; static ataxia, absence of patellar reflexes, and which was further complicated by a glycosuria, a traumatic neurosis, and a railway damage suit and, one instance wherein neuritic pains were eased by arsphenamin, one observes that none of these patients presented symptoms that could be interpreted as characteristically syphilitic in origin. No actual paralysis existed and barring one case no deep tendon reflexes were absent. Pupillary reactions were sometimes slight, a condition easily attributable to generalized arteriosclerosis; the sometime exaggerated patellar reflexes might be accounted for by the same condition. I in no way gained the impression that Parkinson's disease is a phase of syphilis. However, what seemed plausible is a belief that lues may be a determining factor in the disease by effecting loss in organic defense to a virus which finds its most potent expression in characteristic tissue change, namely: degeneration to a greater or less extent of the corpora striata. Syphilis and arteriosclerosis and in turn a generalized arteriosclerosis and Parkinson's disease have long been regarded as closely connected. I do not recall, however, that preeminent frequency of previous luetic infection and paralysis agitans has elsewhere been remarked upon.

I am entirely aware that a presumptive diagnosis of sometime infection of lues based upon cutaneous scars may be precarious. It is less so in temperate than in tropical countries or where crowded housing conditions prevail with consequent greater chance of skin ulceration from extrinsic causes. When due regard has been paid to exclude other conditions in which multiple deep rounded cutaneous scars may appear, their presence with smooth yet sharp contours has proven of value as clinical evidence of previous infection in many instances. Taken alone, I would give them more weight than a positive Wassermann without clinical symptoms. I submit the following histories as pertinent to their importance, particularly in cases presenting no characteristic paralyses or changes in tendon redexes.

CASE A.—Woman aged 28 yrs.; married 10 years. Some diseases of childhood all completely recovered from. Was always overworked. At 17 years a breakdown with fever upon any exertion; afternoon temperature 101° to 103° F., no cough or expectoration. Moved from Arkansas to Arizona on account of her mother's illness, diagnosed tuberculosis. After marriage pain over both ovaries. Pregnant four months after marriage. When seven months pregnant was in a runaway accident. Miscarriage threatened, to avoid which the patient remained in bed until the child was delivered at full term. This child is an attractive although not robust girl of nine years. Second pregnancy nine months later; miscarried at three months. Third p nancy six months later; miscarried at three months. Fourth pregnancy interrupted by miscarriage at three months. During her fifth pregnancy the patient was very ill. Much pain in stomach and abdomen. Remained in bed for five months when a child was born at more than full term. During this pregnancy, at four months one cystic ovary was removed. Hemorrhages continuing, the second ovary was removed after childbirth. Hemorrhages then ceased. This second child is also living and is moreover a screen star of first magnitude. When first seen, the patient complained of "sore stomach," indigestion, constant desire for water, morning nausea, and headache. Griping pains at times in the left side of the abdomen. Physical examination disclosed a woman in good flesh, some acne varioliformis of the face. Pupils are small but they react to light and accommodation. Occasional râles of medium intensity in the left upper and right middle lobes. Upon palpation the pit of the stomach is not tender but the upper left abdominal quadrant is very sensitive to pressure, also both right and left lower quadrants. Small scars (not of acne) on the left arm, characteristic luetic scars at and below both knees; one very large round scar on the right leg. Urine negative. Alternating doses of potassium iodide and mixed treatment (without iodine) put this patient in excellent condition in sixty days.

CASE B.—A married woman of 35 yrs. Two children of respectively 8 and 14 years of age. One miscarriage induced. Has always been well. Formerly an amateur champion in a certain line of athletics. Two years previously pain in the right knee. This improved but six months later pain in the right leg as well as the knee. Slight pain in the right shoulder. The leg has given way at times. Present complaint is pain above the outer condyle of the right tibia and adjacent region, the back of this leg and the thigh up to the sciatic notch. The patient limps to spare this extremity. Occasional headache. Constipation. No bladder symptoms. Physical examination discloses a well developed physique. Muscular power of limbs good but the right arm and leg are somewhat smaller than those on the opposite side. Pupils react to light and accommodation. Patellar and achilles reflexes present. No Babinski. Small scar at the edge of the right brow, several of characteristic type on the left arm (vaccination scar on the right arm); one large deep scar showing loss of much tissue substance at the right knee. Urine 1005, alkaline, albumin a trace, sugar negative. Prescribed laxatives and at alternate periods solution of potassium iodide and mixed treatment by mouth. The patient began to improve immediately; was under treatment nine weeks. She has remained well.

CASE C.—Married woman aged 55 yrs., a nurse. History of inflammatory rheumatism immediately after marriage. Was four months in bed. Pregnant three times; two still births at seven months. The third child lived four weeks. For the past five months pain in the shoulders, especially on the right side. Physical examination: Pupils react to light and accommodation. A systolic aortic murmur. No Babinski. One characteristic scar on right tibia, two upon the back near the scapulæ and one on the left flank. Systolic pressure 195, diastolic 95. Seven and one-half grains of potassium iodide three times a day reduced the systolic pressure to 135 mm., the diastolic pressure remaining 95 mm. The patient felt less well at this approximately normal pressure than she did with the systolic reduced to but 175 mm., so she was placed on mixed treatment (without iodine), upon which she did well. She has steadily followed her profession, even during a very strenuous period of the influenza epidemic.

As against these instances *in which the dominant symptom complained of was pain, the interpretation of which was influenced by presence of characteristic cutaneous scars,* the following case is of interest.

CASE D.—Woman, aged 33 years; married three times. One child by her first husband, which is living and well. Describes her second husband as "gay."

During this marriage gonorrhea, also a tumor in the urethra diagnosed soft chancre. The latter did not yield to treatment, but gradually disappeared. Shingles eight months previously. Has severe headaches and pain in both eyes. Feels constantly in danger of falling because she cannot properly use her right leg. She says "it drags," although this is not noticeable. Patient makes patent effort to enunciate plainly. Sometimes she uses the wrong substantive, immediately, however, recognizing the error. Wants to sleep a good deal; of good appearance, but somewhat overstout. Action of external ocular muscles intact. Both pupils widely dilated and present the Argyle-Robertson phenomenon. Both optic discs are paper white, clearly outlined; the normal cupping has disappeared. The retinal vessels are greatly dilated. When standing the patient sways backwards or forwards, often reaching for support. Patellar reflexes exaggerated; no Babinski. Tested against resistance, muscular strength of all extremities fair to good. Comparatively less strength in right arm than right leg. Sensation to touch and pain apparently normal. With exception of a vaccination scar, the skin is smooth and without a blemish. Temperature normal, pulse 82. Systolic pressure 90 mm.; diastolic 65 mm. Blood Wassermann negative. The history, together with the objective symptoms, permitted the diagnosis of cerebral syphilis. After one intravenous injection of 0.6 neoarsphenamin all symptoms disappeared except persisting but lessened pain in the eyes. I last saw the patient just previous to a second injection of the same remedy.

The point I wish to make is this. This patient passed from her initial lesion to an acute cerebral syphilis without noticeable or, at least, any persisting cutaneous sign; also the outstanding feature of her complaint for her and her environment was a monoplegic disability pointing to cerebral origin, a fact to which the Argyle-Robertson phenomenon testified as well. After a single intravenous injection, the pupils began to contract and the patient had regained full control of her right leg. With pupillary symptoms of recent origin, vigorous antisyphilitic may right them entirely or in a similar case, the Argyle-Robertson pupil might never be a part of the clinical picture. Such a patient seen at a later period may perhaps complain solely of pain and consequent disability as in cases a, b, and c. With associated lack of characteristic paralysis or involvement of the deep reflexes as in the cases cited, the unblemished skin would mean absence of an important diagnostic clue. The Wassermann reaction may at times assist in establishing the true etiology of chronic pain. But even so, late syphilis often shows a negative blood or spinal fluid reaction. Also, as regards cerebral lues, Head and Fearnsides[1] after an exhaustive research pointed out that a positive Wassermann is rare at any stage of meningovascular syphilis so localized.

417 MARINE BANK BUILDING.

Influenza and Sleeping Sickness.—Reich relates that a patient who had recently recovered from lethargic encephalitis was attacked by severe influenza after having been exposed to patients with the same malady. This case seems to exclude the possibility that these two affections have anything in common. However, Rumpf, who saw a number of cases of lethargic encephalitis last spring and summer, states that in nearly every case encephalitis occurred in the wake of influenza. The mortality was high.—*Schweizerische medizinische Wochenschrift.*

NERVOUS AND MENTAL MECHANISMS: THE NERVE IMPULSE.

BY WILLIAM STEINACH, A.B., M.D.,

NEW YORK.

LECTURER ON NEUROLOGY, UNIVERSITY AND BELLEVUE MEDICAL COLLEGE; ATTENDING NEUROLOGIST, CITY HOSPITAL, BLACKWELL'S ISLAND.

MANY facts in medicine have been accepted as axiomatic without question. An assumption is made and handed down from generation to generation until it is forgotten that it is a mere theory, and is accepted as a proven fact. Thus has arisen the idea of the nature of the nerve impulse. For many years, the older physiologists believed that the nerves were tubes through which flowed fine matter like air or gas known as animal spirits. "With Galvani's discovery of electricity," says Howell in his Physiology, "the nerve principle as it was called, became identified with electricity, and indeed the view, as it will be explained, prevails in modified form to-day." The exact nature of the nerve impulse even to this day has not been proven, and many of our ideas of the function of the nervous system have been based on an unproved assumption. A short time ago, in studying the anatomical and physiological basis for some of our psychological processes and endeavoring to correlate structure with mental processes, the writer was impressed with the inadequacy of many of our present day conceptions. As an example, the process of recalling past memories, presents insuperable difficulties of explanation, if we accept the present day idea of the neuron as a conductor. When an afferent impulse reaches the brain, a large number of memories of various kinds are aroused, which were stored through association fibers with former impressions, and brought into consciousness. This would mean innumerable connections by the neurons and would entail scores of combinations and a contiguity of so many neurons that the matter is inconceivable of being possible. At the present time we assume that the individual neurons are distinct from each other, are not continuous but contiguous. In other words, when we see or hear anything, in order to recognize what we perceive, it is necessary to assume that present afferent impressions must make connections with a large number of neurons which were concerned in the past with that particular impression. This would necessitate a selection of so many neurons and associations for one given sensory impulse that it seems improbable. In looking for a more logical explanation of these phenomena, on purely anatomical grounds, the idea occurred to me that, inasmuch as the nerve impulse within the brain is not unlike that in the peripheral nerves, perhaps an investigation of the known facts regarding the nature of the nerve impulse might throw some light on the matter. Accordingly a study of the minute anatomy and physiology of the nerve and nerve impulse was made.

The whole physiological mechanism of the nervous system is based on the assumption that the nerve impulse is of a character analogous to the electric current and that every impulse is conveyed by a species of conduction, implying that there must be an actual touching of the various neurons and

that conduction can only occur when the several neurons are in contact.

It has been assumed that inasmuch as the nerve fibril is enclosed in the neurolemma and myelin sheath, the purpose of these was to insulate, as in the case of an electric conductor, and prevent the dissipation of the impulse in aberrant directions. A study of the anatomy of the nerve fibre reveals that the intimate nerve fibril or axone is contained in a neurilemma composed of horny substance analogous to the nails, called neurokeratin, and that this sheath extends along the nerve fibril up to the juncture with the nerve cell where it ceases. This sheath of Schwann as it is called, is filled with a fat-like substance or myelin and is interrupted at the nodes of Ranvier about 90 microns apart in an average nerve. The neurilemma is nucleated and has partitions going into the myelin cavity, composed very likely of the same neurokeratin, called the incisures of Schmidt. The myelin sheath regularly ends at the nerve cell into which the impulses go, and furthermore many of the nerves of the brain and spinal cord have no myelin sheaths at all; nor do the fibres of the sympathetic system have any. If we are to assume, as has been done, that the nerve impulse is of a conductive character, analogous to electricity, we encounter, at once an almost insuperable difficulty in that the impulse would be dissipated when the insulation disappeared, as in the case of an electric apparatus like an induction coil. If the insulation of the wires disappears, short circuits occur and the instrument becomes incapable of functioning.

The nature of the nerve impulse seemed to me to need further study and our conception of its being conductive in character, seemed to be an assumption which the known facts of physiology did not warrant. A further well-known phenomenon of nervous pathology also discredits the conception that the nerve impulse is conductive, in that pressure over the nerve will prevent the passage of the impulse for the time being. In a wire or other conductor, pressure however great will not prevent the conduction of the current provided the continuity is not broken or the insulation disturbed. All the known facts of pathology—lesions of the brain and nerves confirm this. Hemorrhage or tumors of the brain or spinal cord will give symptoms as long as the pressure continues, and removal will restore function where no actual tissue has been destroyed. All our surgical therapeutics of brain and spinal cord, as well as nerves, is based on this fact which is inconsistent with the nerve impulse being conductive. Furthermore, in the ear, vibratory sound waves are converted in the organ of Corti into nerve impulses conveyed later to the cerebal cortex. Likewise in the retina, light waves appear to be translated into nerve impulses which are conveyed to the brain through the optic nerves. The rod and cone layer of the retina lends itself readily to this conception in that some of the fibres being in tension would have the protoplasm at one end and appear as cones, and others, relaxed, where the material was equally distributed along the length of the fibre would appear as rods. From these analogies, it occurred to me that the nerve impulse is probably *vibratory*, analogous to sound vibrations, rather than *conductive* like electricity, and an analysis of many of the known facts of the physiology of the nervous system seems to favor this and afford a better explanation of many of the nervous and mental processes than does the conductive theory.

The velocity of the nerve impulse, as ascertained by Helmholtz and accepted by physiologists generally is that it travels about 34 metres or 106 feet per second. Electricity travels many thousands of miles per second; light, about 186,000 miles per second; sound waves travel 1,090 feet in air and 4,708 in water per second; in glass, 14,850; in iron, 16,820. The velocity of sound vibrations has been determined to be directly proportioned to the square root of the elasticity of the medium divided by the density as expressed by the formula,

$$V = \sqrt{\frac{E}{D}}$$

in which V represents the velocity, D the density, and E the modulus of elasticity or power of regaining its shaps after compression. The modulus of elasticity of protoplasm of all kinds is very low compared with water or air, and the density higher so that one would expect the velocity of the nerve impuse, if it were vibratory like sound, to be a great deal less than the sound wave in water or air. I have been unable to obtain exact figures for the modulus of elsticity of nerve tissue, but its density is much above that of air and greater than water.

A number of other facts that have been ascertained regarding the nerve impulse also appear to confirm the vibratory theory more than the conductive hypothesis. At all events none that I have encountered so far appears to be inconsistent with this view.

When a nerve is stimulated and immediately after, another impulse is sent along the nerve, the second interferes with the first, giving rise to what is termed the refractory period. This is exactly what takes place in a vibrating musical string. A short time after the refractory period, there appears, according to Keith Lucas, a supernormal excitability, in that the same stimulus gives a greater impulse. This again is exactly what one would expect in a vibrating nerve, when the bed in which the nerve fibril lies in the neurilemma is somewhat loosened up from the former impulse after the effects of interference have disappeared.

Sound waves in air can be refracted and reflected by a lens just as light. The familiar experiment of making a lens of air or gas with a rubber balloon, as described in all elementary books on physics, and placing a watch at one focus permits the hearing of the sound loudest at the other focus, is no doubt familiar to many. In other words, vibratory impulses, like sound or light, are capable of being refracted in passing from one medium to another of different density. Remembering this, if we regard the nerve impulse as vibratory, in passing into a cell it will be refracted as by a lens or prism. Most of the motor cells appear to have rather a triangular outline and the sensory cells are mostly oval. This might be very suggestive and it is not improbable that the cell body may have some function in refracting the impulse from the dendrites into the axis cylinder, to be passed along to the

end organ in the muscle or gland, or in the case of afferent fibres to the cortex. The sensory end organs in the skin, the Pacinian bodies, are concentric layers of membrane which appear to be consistent with the idea of starting up vibratory stimuli.

A number of other nervous and mental mechanisms can also be better explained by a vibratory than a conductive theory. We know that when one string vibrates in the vicinity of other strings, the latter even though not in contact will vibrate in unison if properly attuned. Thus if an E string on the violin is struck, and several harps or a piano be near, the corresponding strings on the latter will vibrate in unison, *i.e.* the E strings will vibrate in all. This would lend a ready explanation for the storing and reviving of impressions in the brain. If one neuron of the brain was vibrating, a number of others properly attuned would vibrate in unison and many impressions could be stored up in memory or revived from the vibrations of one neuron. This appears to me to explain the method of storing up impressions much better than those heretofore proposed. Furthermore, vibrations of a definite character would always be stored up by the neurons of the proper length and tension in the same part of the cortex and would not be inconsistent with our ideas of cerebral localization. Again the structure of the cortex with its six layers of neurons would readily favor such a view. The dendrites might be likened to the antennæ of the wireless apparatus which pick up the vibrations of a definite length and direct them through the nerve cell to the axone. The cells of Purkinje in the cerebellum, whose function we assume to be largely coordinating, are again suggestive and rather favor the vibratory viewpoint.

Again, the fact that the brain is enclosed in a rigid bony box without any openings to the external air directly suggests a sounding box; at all events it is well adapted to protect from outside vibrations.

When a nerve is cut across and the ends sewed together, restoration of function in a motor nerve does not occur according to Sherren until from three weeks to sixteen months after the operation. This again favors the vibratory idea. If the impulse were conductive, restoration of function should occur immediately after repair, as would happen in an electrical conductor. The current again passes as soon as continuity is established.

This whole discussion is offered in a tentative way. It needs much further experimentation in the laboratory before it can be accepted. However, it appears to explain many of the phenomena of nervous action in a better way than present theories. Perhaps further study may point the way to therapeutic application. It certainly would explain many of the psychoneurotic symptoms if one conceives the tuning of the neurons to be disturbed by toxic or other causes. At all events before proper treatment can be instituted in any organ it is absolutely essential that the physiological functions be accurately known and studied.

Conclusions.—The evidence favoring the vibratory theory of the nerve impulse rather than the conductive, analogous to the electric current, may be summarized as follows:

1. Pressure on the nerve will prevent passage of impulse. Should have no effect on a conductor.
2. If the nerve is cut across impulse will not pass for weeks after union has been made and the nerve is sewed together. If conductive, impulse should immediately pass after continuity is restored.
3. The velocity of nerve impulse, 106 feet per second, is more like that of sound. It also appears to follow the physical law of sound velocity.
4. The refractory period of the nerve is better explained; also supernormal excitability.

RIPE OLIVES.

By DOUGLASS W. MONTGOMERY, M.D.,

San Francisco.

Olives are designated as being either green, or ripe and black. The terms "ripe olive" and "black olive" are synonymous, as an old English writer says, "The more black oliues ben without, the more rype they be within."

In an enumeration of a vast number of things to eat, mostly of the hors d'œuvres variety, Rabelais mentions "olives colymbades," that is to say, olives swimming in their oil.[1] And there are very few dishes more suave or more pleasant than olives so prepared, and eaten with French bread and without butter, as butter in this situation constitutes a superfluity of fat. As a hors d'œuvre also this is excellent, and those who become accustomed to this dish feel its absence. The black olive is the one employed in this situation.

To begin with, the large black olive so praised by Horace,[2] is, to my mind, far and away better than the salty, bitter, green ones, the only variety I knew when I lived in the Eastern States, where they were employed largely on account of their commercial value as a thirst producer.

If, by steeping, the excess of salt is removed from a few fine, large, black olives, and they are then placed in a shallow fruit jar, and enough good olive oil is poured over them to immerse them, and so justify the name Rabelais gives them,[3] and a section of garlic, a so-called "clove of garlic," is dropped in with them, and they are allowed to stand a short time until the flavor disperses, they may be taken out and eaten with a smacking of the lips that it is a joy to hear, and as they must be picked up with the fingers, these are licked also, which is no mean enjoyment.

After a time the taste of the garlic in the oil becomes too pronounced; then the jar should be emptied, but with due care not to waste the oil, which if good, costs more than its weight in silver. This oil may be used in making lettuce salad, in which its garlic flavor regains its delightfulness because reduced to delicate, tasteful proportion.

But, olive oil! It is not always that one can obtain it. Not long since, I traveled from San Francisco to the Atlantic littoral, and by a most devious route, and I did not loiter in the worst hotels or restaurants either, but, according to my tongue and palate, I did not encounter one drop of olive oil during the entire journey. That which I got was not the oil of gladness, oleum exultationis, mentioned so effusively by St. Paul.[4] The hotel keepers

in his day were not so sophisticated, and cotton seed oil was not discovered until long after.

Olives, so prepared, are excellent, not alone as a comestible, but also medicinally, as they afford an excellent way of giving oil, agreeable to the stomach and readily digestible.

Emerson has remarked that the taste for sea-life, like that for tomatoes and olives, is acquired.[4] An initiation may be requisite for the enjoyment of the green olive, but scarcely for the ripe variety when expertly prepared and served in olive oil. No more apprenticeship is requisite for these than for a babe for milk.

Of course, Emerson may have written the above before his visit to the Pacific Coast, and even while in San Francisco, the dish may have escaped him because of too close association with Unitarians, who, coming for the most part from New England, were naturally unaware of this succulent dish.

Recently people have become nervous about black olives, because of several instances of botulism traced to eating bad ones. The incidents attracted a great deal of attention, partly because of the name—in these prohibition days any name sounding like bottle does so. Almost any deteriorated food, however, may cause distress, or even fatal poisoning, and the cases of botulism seem to have been very few indeed. Not long ago, while seated at dinner beside a timorous person, I noticed she did not eat her black olives. She mentioned her fear; I asked how many people, say in New York, were poisoned. I think she said three. As there are about five million people in New York, this represented three five-millionths of a chance. I told her she was no sport, and finished her olives as well as my own.

Medicolegal Notes.

Labeling of Proprietary Compounds Containing Poisons.—The Minnesota Supreme Court holds that, in the absence of some statutory obligation, a vendor of another's proprietary compound owes no duty to the purchaser or the public to ascertain whether it contains ingredients that may be harmful or dangerous if the compound be used for purposes other than those for which it was designed. But a manufacturer of an article or compound imminently dangerous in kind owes to the public a positive and active duty to limit the danger, by labeling or otherwise, conveying knowledge of the danger; and a like duty rests upon a vendor who knows of the dangerous qualities of the article sold by him, and knows that its label or name does not adequately convey knowledge to the purchaser or public of such danger. Applying these principles in an action for wrongful death alleged to have been caused by roach poison, the complaint was held defective in not alleging that the compound sold was imminently dangerous, and in alleging in the alternative that the defendant knew, or in the exercise of due care ought to have known, of the dangerous qualities, and in failing to allege positively the misleading or defective character of the label.—McCrossin v. Noyes (Minn.) 173 N. W. 566.

Warning Minor Patient's Parents of Infectious Disease.—Appeal was made from an order of the trial court overruling a demurrer to a complaint against a physician on the ground that no cause of action was stated. The trial court certified that the question raised was important and doubtful. In substance, the complaint alleged that the defendant was a practising physician, employed by the plaintiff and his wife to treat their minor daughter. Other allegations were as follows: The defendant knew that the disease from which the child was suffering was scarlet fever and that it was infectious. The plaintiff's wife, acting in his and her own behalf, consulted the defendant as to the nature of the disease and the danger of infection. The defendant wrongfully and negligently advised her that they might safely visit their child, who was then at a hospital under his care. He negligently permitted them to visit the child at the hospital, and later on wrongfully and negligently advised the plaintiff's wife that she could be safely removed from the hospital to her home, and that there was no danger that the disease would be communicated, although it was then at the "peeling off" stage, when the greatest danger of infection exists. In reliance upon the defendant's advice, the child was removed to her home. Neither the plaintiff nor his wife knew of the infectious nature of the disease. Both relied on the defendant's advice in visiting their child and in taking her home. By reason of their contact with her, both contracted scarlet fever, and the plaintiff suffered pain and was kept from his work for many weeks, to his damage in the sum of $1,000.

The Minnesota Supreme Court, regarding the case as a novel one, held that the trial court properly overruled the demurrer, applying the principle that, generally speaking, one is responsible for the direct consequences of his negligent acts whenever he is placed in such a position with regard to another that it is obvious that if he does not use due care in his own conduct he will cause injury to that person; although it conceded that it might be true, as suggested by the defendant's counsel, that it is a matter of common knowledge that scarlet fever is an infectious disease and that the plaintiff might not have been greatly influenced by the defendant's alleged assurance that he might visit his child or take her to his home without running any risk of infection.—Skillings v. Allen, Minnesota Supreme Court, 173, N. W. 663.

Cold a Disease within Question as to Previous Medical Attendances.—The law that misrepresentations do not void a policy unless material to the risk or actually contribute to the contingency has no reference and does not apply to fraternal benefit societies. An insurance policy of a fraternal order, making it the duty of the examining doctor to require an answer to every question, and to explain the meaning of terms used, does not give the doctor the right not to require an answer to the questions as to previous medical attendance because he may not have thought the thing for which he previously prescribed and treated the applicant was a disease within the meaning of the term as used. The word "disease" as used in such an insurance contract and application question is held to comprehend a cold and fever, being a morbid condition of body, and having as synonyms "disorder," "distemper," and "malady."—Sovereign Camp v. Treanor, Texas Civil Appeals, 217 S. W. 204.

Evidence of Causal Connection Between Negligence and Injury.—In a malpractice case, the negligence of defendant physicians and the causal connection between such negligence and the injury may be established by circumstantial evidence and inferences legitimately drawn from physical facts. In such a case, evidence that, the day after the plaintiff had a kidney removed, the defendant physician had one of his teeth pulled, breaking his jaw, and that they did not reset the jaw or otherwise treat his mouth to stop a soreness and discharge which lasted until he secured another physician was held to make the defendants' negligence and the question whether such negligence caused the plaintiff's injury a question for the jury.—Eichholz v. Poe, Missouri Supreme Court, 217 S. W. 282.

THE PATHOGENESIS OF PEDUNCULAR AND BULBO-PROTUBERANTIAL SYNDROMES IN TYPHOID FEVER.

THE nature of these paralyses is still obscure, but it seems quite clear that they are not due to a typhoid meningitis at the base. There may, perhaps, be a simple toxic encephalomyelitic reaction at work, but as Moizard and Greult have have pointed out, the process is almost hopelessly difficult to discover. The symptoms refer to both the cortex and the cord, so that there are headache, vomiting, stiff neck, Kernig's sign, and disturbances of the respiratory and cardiac rhythm. Ocular disturbances are rare in meningism, but the principal argument will be drawn from the cerebrospinal fluid, which, however, may be negative. In one case recently reported by Collet, there was no hypertension, polynucleosis, lymphocytosis, or albumin, and the fluid was clear. However, Widal has referred to cases with meningeal syndromes in which the cerebrospinal fluid was clear and devoid of cell elements. If meningitis be eliminated, to what cause can these paralyses be attributed? Few autopsies have been made in these cases and anatomical examination has revealed nothing. Consequently, we can explain the origin of the peduncular syndrome only along the same lines as the theories proposed for typhoid paraplegia. For some, these are the result of a peripheral neuritis caused by typhoid toxins and this opinion is based upon the coexistence of paralysis of a peripheral nerve, as has been met with in some cases. Others maintain that the central nervous system is involved; there are bulbar lesions which could explain the association of some other cranial paralyses, such as those of the velum pendulum palati for example.

Mere reference need be made to the opinion of observers who incriminate either muscular or articular lesions of the larynx or who regard these paralyses as hysterical in nature. It would appear to be a matter of some difficulty to differentiate the two orders of phenomena, which even clinically are often obscure as to what may belong to a central lesion and what belongs to a neuritic lesion; and with a number of competent observers it seems at present preferable to associate the two orders of lesions, the nerve and the nerve cell, in reality forming a portion of the same whole, influencing each other and capable of being mistaken one for the other. It is, therefore, to a cellulo-neuritis that the bulbo-protuberantial paralytic disturbances should be attributed, the consequence of total changes of both portions of the neuron; but it is to be hoped that future research may establish this opinion, which can as yet be regarded only as a mere hypothesis. In a case observed by Lépins, of Lyons, there was a hemorrhagic softening with congestion around the focus of softening and an invasion of the cord in lines following the track of the dilated vessels. Involvement of the radicular cells of the gray matter appeared to be more important than that of the cells of the white matter. There was likewise a very marked infiltration of the meninges.

Vincent's experimental results appear to confirm these findings. After inoculation of a rabbit with typhoid bacilli and another bacterium, medullary symptoms were produced resembling those of Landry's disease. The animal died at the end of forty-eight hours and at autopsy a change in the cells of the cord was found, with tumefaction of the axis-cylinders, proliferation of the neurogliar and endothelial cells and capillaries. Some of the dilated capillaries had ruptured. A number of other observers have studied these experimental lesions of typhoid fever and it seems logical to admit from their combined findings that the action of the bacillus or its toxins on the nerve cell or cord results in a disintegration and disappearance of the chromatic substance of the cells, an eccentricity of the nucleus, and changes in the nucleus and nucleolus. This chromatolysis may be confined to the periphery of the cell.

EARLY DIAGNOSIS.

THE old order is changing in the practice of medicine, and as yet the new order has not fully come in; it is only now knocking at the door. Prevention of disease is the medicine of the future, but not altogether in the sense that the term preventive medicine is usually understood. A great deal of the medicine of the future will be preventive as understood by Sir James Mackenzie, that is learning to interpret the meaning of the earliest symptoms of disease, and so to treat them that they do not go any further. Sir Bruce Bruce-Porter, writing in *The Practitioner* of June, 1920, would like to divide medicine, as it appears to him, into (1.) Preventive, (2.) Diagnostic, and (3.) Curative. He points out that the field of preventive medicine is mainly that of the public health officer, who himself in turn must depend upon the next branch, namely, that of the diagnostician, for early notification of disease of a preventable and infectious nature. The curative branch is, in his estimation, the least important of the three. Many medical ailments at present get well in spite of the physician, and all who practice have lived long enough in medicine to see many vaunted specifics proved of no value. The

most important thing is correct and early diagnosis, and it is recognized that many serious illnesses would be avoided by earlier recognition of the symptoms. Porter draws attention to what is undoubtedly often true that the ordinary patient expects too much from a medical man, he expects to walk into the physician's consulting room and come out in a few minutes with some hieroglyphics on paper guaranteed to cure. Again, the average patient does not consult a doctor until something has gone wrong with his works, and then consults someone who has been recommended to him by a chance friend or acquaintance. The doctor has never seen him before, during his normal state, so cannot possibly say how far he has departed from it. There is no doubt whatever that early diagnosis is the surest preventive of disease, that is, so far as the medical man in his direct capacity of healer is concerned; quick and correct diagnosis marks the great physician. If then early diagnosis is the sign manual of the capable physician, every nerve should be strained to make of the medical man a rapid and reliable diagnostician, and every means should be used to induce those who are not feeling well to consult the doctor before flying for relief to patent medicines.

As regards the training of the medical profession, it appears that Sir James Mackenzie is proceeding along the proper lines. He is establishing centers at which medical men will be trained to detect the earliest symptoms of disease and to prevent them from going further. But unless the public will cooperate with the medical profession and consult a medical man early, much of this time spent in training, while it will not have been wasted, will not have been put to its best use. Therefore, the public must be educated to consult a doctor for their minor ills, as well as their major ones, since it is the former which treatment often can control before they have become transformed into the latter.

Anomalies of the Spine.

THE anomalies arising in the vertebrae and spine are of two sorts: numerical anomalies and morphological anomalies. The former are sufficiently extensive to produce a deformity of the spine in very rare cases only. Usually confined to a single vertebra, they are of interest to neither the anatomist nor the clinician. The second, however, almost invariably produce deviations of the spine and are of clinical interest, and their study, which had been greatly neglected, has now been made easy by the development of radiography. These morphological anomalies may be seated anywhere along the vertebral column, but they seem to have a particular liking for the cervicodorsal and still more especially for the lumbosacral regions. The principal defects met with clinically are: a wedge-shaped deformity of a vertebra, due either to simple atrophy or to a complete defect of development of one-half of a vertebra; the division of a vertebral body into two portions which are generally unequal; the suture of one side of a vertebra to the corresponding side of a neighboring vertebra, and lastly, the development of the cervical rib. These vertebral malformations should be generally known, because clinically they ordinarily bring about deformities of the spinal column—generally scolioses—and, when the anomaly involves the lumbosacral vertebrae, the result is a deformity of the pelvis which will interfere with labor. A precise diagnosis of these various conditions can be made only by radiography, and in questions of deformity of the vertebral column, radiography is quite as essential as in all bone pathology. From the viewpoint of treatment, the verification of these anomalies has given rise to a great change in the therapeutics of spinal deviations. In some cases a surgical interference is quite justifiable, not only in the case of cervical ribs, but also in instances of vicious synostosis.

To Him That Hath.

THE young doctor who sits in his office all day, feet on desk, waiting for patients, is passing. Let him go; and may the place thereof know him no more. In these days of preventive medicine, of statistical study, of research, more and more "jobs" with pay are available for the energetic young M. D. with adequate training. And if he is sensible enough to realize the advantages of dispensary work, opportunities for seeing cases and doing original work are abundant. In other words he cannot only seem busy, but must be the thing he seems. Every medical graduate should be given a card, reading, "If you would get patients, get busy." It is a matter of pride with the layman to be able to say of his doctor, "He is awfully busy; always on the go; more to do than he can handle; better call him in." Lay standards are such that big business gets bigger. It is as true of medicine as it is of oil or steel. To him that hath shall be given. Of the young man in the incipient stages of practice, it may safely be said that he "hath nothing" but an M. D. and a license. What these are worth depends upon the individual—except in the case of him who has a pull with some older man who "hath." Advertising, that time-honored "starter" on which our lay friends depend for launching a new venture, is rightly withheld from the young professional man who has skill, not wares, to sell. For honesty and industry, those two cardinal virtues in medicine, have no disposition to advertise, to claim authority, to display.

To become known through hard work is the only safe road to publicity open to the young medical man. Let him take any job that comes along, provided it will increase his value to the profession. Let him spend himself and be spent on it. And unless we mistake the signs of the times, patients and opportunities galore will be added unto him.

Salicylates in Acute Rheumatic Fever

AT one time the salicylates were regarded almost as specifics for rheumatism. Then while they did not fall exactly into disrepute, they were deposed from their former high therapeutic pedestal. At the present time salicylate therapy is looked upon as useful in the treatment of rheumatism but secondary on the whole to diet, except for acute rheumatic fever, in which form of the disease its effects

are often striking. Dr. Paul D. White, writing in the *American Journal of the Medical Sciences* for May, 1920, is enthusiastic concerning the results of salicylate treatment of acute rheumatism. He had seventy-three soldiers under his charge at U. S. Base Hospital No. 6, and states that the most striking lesson learned from the series of cases of acute rheumatic fever at the hospital was the remarkable response to forced salicylate treatment. Almost invariably there was an abrupt ending of joint pain, swelling, fever, and malaise. White remarks that at one time there were two wards full of cases of rheumatic fever. Salicylates were given in large doses to patients in one ward. It was their only medicinal treatment, and they did wonderfully well. The other patients in the other ward were given no salicylates internally at first, but received local treatment and phenacetin and veronal by the mouth. Their pain and discomfort were dulled to a slight degree, but after two or three days of suffering the salicylates were given to them in large doses, followed by great and rapid relief.

News of the Week.

Rat-Extermination and Rat-Proofing Campaigns Urged.—Surgeon-General Hugh S. Cumming of the Public Health Service, in view of the discovery of bubonic plague in several American and Mexican Gulf ports, urges communities throughout the country, especially along the coast, to inaugurate campaigns for the extermination of rats and other rodents. According to Dr. Cummings, foci of infection exist at present at New Orleans, Pensacola and Galveston, and in Tampico and Vera Cruz, Mexico, the disease having assumed the proportions of an epidemic at Vera Cruz.

Drug Clinics Pronounced a Failure.—The Bureau of Internal Revenue, which is charged with the administration of the Harrison Antinarcotic act, will not lend further indorsement to public clinics for the treatment and cure of drug addicts, Prohibition Commissioner John F. Kramer, giving as his reason for this action that "The net results obtained through the operation of such public clinics appear to have demonstrated conclusively that the cure of drug addiction through such means is a failure, and that hereafter no similar institution should have the indorsement of this bureau."

Another Narcotic Drug Cache Discovered.—Narcotics valued at $250,000 were discovered recently by the Italian police squad in the homes of three Italians in Brooklyn. One of the men is said to have told the police that at least 500 persons were involved in a wholesale traffic in smuggled drugs along the Brooklyn water front.

Typhus in Poland.—According to a statement recently made by the director of the largest Jewish hospital at Kiev to Colonel Henry Shaw, of the American Army, who is investigating deaths among refugees for the League of Red Cross Societies, 25,000 Jews died of typhus fever within six weeks just prior to the Polish occupation.

Straus Milk Laboratory Accepted by City.—The offer recently made by Nathan Straus to turn over to the city of New York his milk pasteurization laboratory to be used for the benefit of the children of the city on condition that the city provide funds for carrying on and extending the work, has been accepted by the Board of Estimate.

Reports of Plague in Mexico Denied.—The report of two suspected cases of bubonic plague at Cerritos, State of San Luis Potosi, Mexico, has been pronounced incorrect by the president of the board of health of that locality.

Schools for Hospital Attendants.—Bird S. Coler, Commissioner of Public Welfare, was instrumental in the establishment, some time ago, of four schools for the training of hospital attendants. These schools are at the City Neurological Hospital, Blackwell's Island; the New York Children's Hospital, Randall's Island; Sea View Hospital, Staten Island, and Greenpoint Hospital, Brooklyn. The pupils are being instructed in the principles of hospital treatment and how to care for simple and ordinary sick and chronic cases. They are said to be the first schools of the kind to be established.

New Clinics Established.—The Visiting Nurse Service of the Henry Street Settlement, New York City, has announced the establishment of four new clinics in connection with its nursing and medical facilities. Plans for the establishment of a diagnostic clinic are under way.

Doctor Convicted of Manslaughter.—A practising physician of this city has been found guilty of manslaughter in the first degree for the death of a woman patient following an operation alleged to have been unnecessary. The conviction carries with it a penalty of from ten to twenty years' imprisonment.

Jacobi Gift to Academy of Medicine.—Dr. Abraham Jacobi, who died in July of last year, and whose estate has just been appraised, gave $5,000 cash and books worth $4,567 to the New York Academy of Medicine.

Dr. James H. Hyslop, well-known phychologist, and editor of the *Journal of the American Society for Psychical Research,* died on June 17, 1920, of cerebral thrombosis. His brain has recently been given to Dr. Edward A. Spitzka of New York City for scientific study. The brain had not been weighed on removal, but when received by Dr. Spitzka after five days' immersion in 5 per cent formaldehyde solution, its weight was 1290 grams, or 45.5 ounces avoirdupois.

Schick Tests in Colored Children.—The Bulletin of the New York City Department of Health notes that, in performing the Schick test on the pupils of the public schools and in the Baby Health Stations of the Greater City, some difficulty was anticipated in the interpretation of the results of the test in colored children. The question was submitted to the Bureau of Laboratories which, in cooperation with the Division of Institutional Inspection, had had experience with the test in institutions for colored children and the following statement was supplied: "The Schick test was carried out in two institutions caring for colored children. The number tested and re-tested was about 1,000. To interpret the Schick test in the colored child is not much more difficult than in the white child. The redness of the positive reaction, in the first few days, stands out against the rest of the pigmented skin and can, with a little study, be readily seen.

Where there is difficulty, moistening the skin with alcohol and looking at the reaction from a little distance will help a great deal in reading it. In the later stages, the pigmentation and scaling is quite distinct, and stands off from the remainder of the skin by its darker hue. The pseudoreaction can be readily noted and fades quite rapidly, leaving the small irregular blotches of pigmentation."

Dr. Richard Derby of New York City, who served in the medical corps, with the rank of Lieut.-Colonel, was recently awarded the Distinguished Service Medal by the War Department, for "exceptionally meritorious and conspicuous service as Sanitary Inspector of the Second Division and in charge of front line hospital work during operations of the division in the Marne area, and later as Division Surgeon during the Meuse-Argonne offensive."

Dr. Milton C. Winternitz has been elected dean Yale School of Medicine to succeed Dr. George Blumer, who recently resigned. Dr. Winternitz, who was graduated from Johns Hopkins University in 1903, became a member of the Yale faculty in 1917. During the war he was in charge of research in pathology and bacteriology at the Yale Bureau of Mines, later as Major in the Medical Corps, chemical Warfare Service, doing research work in the laboratories at Yale, at Lakehurst, N. J., and at Washington.

Commander William Seaman Bainbridge, U.S.N., R.F., addressed the Montgomery and Chester Counties Medical Society on June 15. The meeting took place in the Washington Inn, Valley Forge, and as an appropriate topic, Commander Bainbridge spoke on "Some of the Surgical and Medical Lessons of the War."

Dr. Christian F. J. Laase of this city, who was indicted some time since for alleged violation of the Harrison antinarcotic law, was tried on Tuesday of this week in the U. S. District Court and was triumphantly acquitted. And so ends this attempt to dictate to educated and honorable physicians in the matter of treatment. We congratulate Dr. Laase.

Rockefeller Foundation Aids Medical Education in England.—The University College and Hospital School, London, have been selected for the execution of the plans of the Rockefeller Foundation for furthering medical education in its efforts "to promote the well-being of mankind throughout the world."

Charitable Bequests.—By the will of the late Lena K. Schlichter of Philadelphia the sum of $250,000 is bequeathed immediately to the Frankford Hospital of Philadelphia, and also a part of the residuary estate.

By the will of the late Elizabeth J. Gwett, of Philadelphia, the sum of $229,200 is bequeathed to the Pennsylvania Hospital as a memorial to her husband, the late Annesley R. Gwett.

By the will of the late Wm. K. Smith, of Philadelphia, the sum of $500 is bequeathed the Children's Homeopathic Hospital of Philadelphia.

Contributions to American Hospital at Neuilly.—George Edward Kessler of St. Louis has given 250,000 francs and Louis D. Beaumont of the Aero Club of America 100,000 francs to the American Hospital at Neuilly, France. The institution to date has received 2,750,000 francs toward the 7,000,000 franc fund being collected for the purpose of enlarging it.

Medical Society Elections.—THE NORTH DAKOTA MEDICAL ASSOCIATION, at its recent annual session at Minot, elected the following officers for the coming year: *President,* Dr. P. W. French, Grand Forks; *First Vice-President,* Dr. A. P. Quain, Bismarck; *Second Vice-President,* Dr. W. C. Fawcett, Starkweather; *Secretary,* Dr. H. J. Row, Lisbon; *Treasurer,* Dr. J. P. Aylen, Fargo. The 1921 meeting will be held at Fargo.

THE NEW HAMPSHIRE HOMEOPATHIC MEDICAL SOCIETY, at its sixty-seventh annual meeting recently held at Laconia, elected the following officers to serve during the ensuing year: *President,* Dr. Maurice E. Wiley, Laconia; *Vice-President,* Dr. Edwin D. Stevens, Francistown; *Secretary,* Dr. Martha I. Boger, Portsmouth; *Treasurer,* Dr. Heman Christophe, Manchester.

THE MICHIGAN STATE MEDICAL SOCIETY, at its fifty-fifth annual meeting, held in Detroit in May, elected the following officers to serve during the coming year: *President,* Dr. Angus McLean, Detroit; *First Vice-President,* Dr. S. A. Crane, Kalamazoo; *Second Vice-President,* Dr. Udo J. Wile, Ann Arbor; *Third Vice-President,* Charles M. Williams, Alpena; *Secretary-Treasurer,* Dr. Frederick Cook Warnshuis, Grand Rapids.

THE NEW ENGLAND FEDERATION OF MEDICAL EXAMINING BOARD, at its meeting June 2, elected the following officers: *President,* Dr. Charles Duncan, Concord, N. H.; *Vice-President,* Dr. M. F. Fallon, Worcester, Mass.; *Secretary,* Dr. S. H. Calderwood, Boston, Mass.

The OHIO ECLECTIC ASSOCIATION, at its recent annual session, elected the following officers for the ensuing year: *President,* Dr. W. E. Lehr, Arlington; *First Vice-President,* Dr. C. V. Holzmary, Farmersville; *Second Vice-President,* Dr. Byron Nellans, Cincinnati; *Secretary,* Dr. J. F. Wuist, Dayton; *Treasurer,* Dr. J. J. Sutter, Lima.

The MEDICAL SOCIETY OF CALIFORNIA at its recent annual meeting held at Santa Barbara elected the following officers for the coming year: *President,* Dr. John A. Graves, San Francisco; *Vice-Presidents,* Dr. William Duffield, Los Angeles, and Dr. Joseph Cotton.

Obituary Notes.—Dr. LOUIS F. SMILEY of Philadelphia died at Chambersburg, Pa., on June 12, at the age of 69 years. He was graduated from Hahnemann Hospital and Medical College in the class of 1875.

Dr. WILLIAM W. ARMSTRONG of New York City died June 12, at the age of fifty-four. He was graduated from Bellevue Hospital Medical College in 1897.

Dr. GEORGE BOARDMAN CORNELL, for forty-six years a practising physician in Brooklyn, N. Y., died June 17 in, his eighty-eighth year. He was graduated from New York University Medical College in 1864, and from New York Homeopathic Medical College and Flower Hospital in 1871. He was a member of the Kings County Medical Society.

Dr. CHARLES TURNER FISKE of Portland, Me., died June 11, after a long illness, at the age of 72.

Dr. JAMES C. BARKER of New Milford, Conn., where he had practised for forty years, died June

16, at the age of 68. He was graduated from Yale University School of Medicine in 1879.

Dr. TREBY W. LYON of New Haven, Conn., died June 14, at the age of 39. He was graduated from Yale University School of Medicine in 1903, specializing proctology. He was a member of the American Medical Association.

Dr. BENJAMIN T. WILSON, formerly of New Bedford, Mass., died recently on his estate on the island of Onjonan, one of the Comoro group, on the east coast of Africa. Dr. Wilson, who was eighty-two years of age at the time of his death, left New Bedford in 1865 on a whaler on a voyage for his health. Landing on the island of Onjonan during an illness of the ruler of the island, who had lost his eyesight, Dr. Wilson, so the story goes, treated the king and restored his eyesight. In appreciation of these services the doctor was given a royal grant of a thousand acres of land, upon which he established himself with an army of retainers. His last visit to the United States was made in 1892.

Dr. CLAUDE H. ADDLEMAN of Whitewater, Ind., who was graduated from the Indiana University School of Medicine on June 1, and who had been serving as interne at the City Hospital, Indianapolis, since February, died June 16 as the result of blood poisoning. He was 26 years of age.

Dr. MARIE G. LANGDON of Englewood Cliffs, N. J., died June 21, at the age of 51. She was graduated from Baltimore University School of Medicine in 1904 and the Woman's Medical College of Pennsylvania in 1905.

Dr. THELESPHORE CHAGNON of Brooklyn, N. Y., died June 22, of apoplexy. He was graduated from the Long Island College Hospital in 1894.

Correspondence.

THERAPEUTIC INFORMATION WANTED.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—Although feebly, in a whisper as it were, the editorial below (from the *Boston Transcript*) speaks for itself, begging answer:

> Investigation in Chicago shows that 500,000 prescriptions calling for whiskey have been written in that city since national prohibition went into effect in January last. . . . Captain Hubert Howard, who is Federal prohibition director for Illinois, has been studying the records, and expresses the opinion that of the half-million prescriptions, 300,000 are evasions of the spirit or the letter of the law. One doctor is said to have admitted that when a regular patient came to him and asked for a prescription for whiskey, it was possible to discover symptoms that justified a pint. . . . This is not, however, a matter that should be lightly treated. The charge that Chicago physicians in less than six months have written 300,000 fraudulent prescriptions is a serious one. While the practice, even if it exists to the extent alleged, is doubtless confined to a minority of the city's medical practitioners, it nevertheless tends to cast discredit on the profession as a whole. It is something calculated to breed contempt for law."

Now, certainly, for the honor of the profession, some therapeutist-with-alcohol, some unofficial Procurator Pauperum (Bibulorum), at length will explain to the expectant physicians the manifold medical necessity for alcohol. Even if only a possible one-half of one per cent. of the half-million prescriptions referred to above were written by conscientious physicians still mindful of their Hippocratic oath, there must be some one of them, or some doctor of like mind nearer by, who will see the pressing need of this wide explanation and give us it—lest the public begin forthwith to think of the physician's office as the modern illegal successor of the kitchen-barroom and of the saloon.

Never a prohibitionist on principle, the present writer is anxious now to see tried out this great prohibitory, hygienic experiment, this colossal biological research; for he is trustful always in the soundly self-protective common sense of the mass of men. But he is still more anxious that the leading public opinion of our land should have much less reason to think "discredit on the profession as a whole." And especially so since alcohol's medical apology is so readily (?) set before the world. Yet if so readily, why is it not promptly done? Or is the claim insincere?

This distinctly is not a matter of "personal liberty" to drink what one would when one desires it, but rather is it just now a question of applied materia medica of deep and pressing social import. Or is it, once more, merely appetite versus therapeutics?

All this coil meanwhile is part of life, our "Magnificent Adventure." During this Pilgrim-anniversary year especially we may be reminded often of J. E. Flecker's already well-known stanza, a sort of hymn for the physician who takes his work and his privileges at something more than those of a trade:

"We are the Pilgrims, master; we shall go
  Always a little further: it may be
Beyond that last blue mountain barred with snow,
  Across that angry or that glimmering sea,
White on a throne or guarded in a cave,
  There lives a prophet who can understand
Why men were born: but surely we are brave
Who make the Golden Journey to Samarkand."

GEORGE VAN NESS DEARBORN.

CAMBRIDGE, MASS.

OUR LONDON LETTER.

(From Our Own Correspondent.)

LONDON, June 4, 1920.

Anthrax in Shaving Brushes.—A paper read at the International Health Conference held recently in Brussels dealt with shaving brushes as a means of spreading anthrax. Surgeon-Commander Bassett-Smith of the British Naval Medical Service read the paper, and he discussed the matter as it concerned the British Navy, but as since the beginning of the war anthrax has broken out in several directions, the question is one of general interest. Surgeon-Commander Bassett-Smith gives as the reason for the comparative prevalence of this infection that some small manufacturers who began to trade after 1914 sold brushes made from Chinese and Russian hair, which is not infrequently infected with anthrax, not being aware of the danger. This carelessness, presumably due to ignorance, has occasioned many fatalities and illustrates the need for an international control, that is, for international police supervision of the kind suggested at the Brussels Conference. Laxness, so far as certain health measures are con-

cerned, constitutes a public menace, and as regards the particular instance in point, it should be made impossible to export to other lands products of the nature of infected material from which shaving brushes are to be made. In the meantime it is as well to draw attention to the fact that anthrax is an especially deadly disease and that every precaution should be taken to avoid infection. For example, all new brushes should be boiled for a period of thirty minutes or so and soaked in antiseptic before use. A more sure means of prevention is that fiber brushes should be used, as it is the hair and hair only which is dangerous.

In connection with Bassett-Smith's paper and an editorial thereon in the London *Times* of May 26 last, the secretary of the British Brush Manufacturers' Association points out what he terms undoubted facts, namely, that no anthrax spores have ever been found in shaving brushes made from pure badger hair or in those made from bristle, *i. e.*, the hair of the pig, and brushes stamped either "pure badger" or "pure bristle" may be used without the least risk of infection. According to this writer, the trouble in respect of anthrax has arisen in connection with brushes containing Siberian, Chinese, or Japanese horse hair, pony hair, or goat hair, and has almost invariably, if not always, been traced to brushes imported from Japan. Moreover, the secretary states that with regard to the dissemination of anthrax infection in Great Britain the onus rests on the government. Hair for shaving brushes brought from Siberia, China, or Japan and used by British manufacturers has to be sterilized before use in accordance with British Home Office regulations, but up to the present time the government has not insisted that brushes containing such hair when manufactured abroad should be accompanied with any guarantee that the hair has been sterilized. However, the British Government has prohibited the entry of Japanese shaving brushes.

A Constructive Policy of National Health.—The Consultative Council on Medical and Allied Services, a part of the organization of the Ministry of Health, was requested by Dr. Addison, the Minister of Health, on its formation, to consider the question of forming a systematized medical service established on a local basis, but applicable, area for area, to the whole country. The Council has just issued an interim report more as an indication of the trend of its deliberations and conclusions than as a final exploration of an obviously immense and intricate problem. The reason for the report being given out now is "in view of the urgency which attaches to the orderly building up of a constructive health policy and the close relationship which exists between medical services and problems connected with the poor law and local government." As may well be imagined, the report is intensely interesting and instructive, almost as much so, perhaps, to American as to English readers. The Ministry of Health is the first experiment, on a large scale, of the application of modern preventive measures, and if the experiment proves successful, similar schemes will be adopted in America and in all civilized countries. The Council begins by stating that changes are necessary because the organization of medicine has become insufficient and because it fails to bring the advantages of medical knowledge to the people. Moreover, it is pointed out that preventive and curative medicine cannot be separated on any sound principle. They must be combined and brought within the sphere of the general practitioner, whose duties should "embrace the work of communal as well as of individual medicine." Medical treatment is becoming more complex, and it stands to reason that in proportion as the complexity of treatment becomes greater, so it grows more difficult for the individual practitioner to cover the entire range of treatment, comprising, as it does, access to such resources as those of bacteriology, biochemistry, radiology and electro-therapeutics. Also the number of patients who can afford to pay for such treatment diminishes in an almost corresponding ratio. Another point is that the public is beginning to recognize the fact that the house is by no means the best place to be in when seriously ill. It is urged that medical services must in the future be rendered "available" for all classes, though available is not to be taken as meaning "free." They will normally be divided into groups: (1) Those which are domiciliary as distinct from those which are institutional; (2) those which are individual as distinct from those which are communal. But all preventive and curative agencies essential to the health of the people should be brought together in close coördination under a single health authority for each area. The principle, then, of the scheme proposed in the interim report is the establishment in the local area of primary and secondary health centers whereby would be placed at the disposal of every person, of whatever grade of society, the advantages of the most effective medical treatment. The primary centers, situated in villages and small towns, would supply a certain amount of hospital accommodation and would be staffed entirely by the general practitioners of the district, and attendance on the patient at his own home or at the medical man's surgery, or what the report terms "domiciliary service," would still remain the basis of general practice. The improvement in treatment would consist in the fact that the technical resources of the primary center would be at the disposal of the doctor. If a patient needed to be treated under hospital conditions, treatment could be continued at the primary center, under the care of his own medical man, and if it was found to be necessary to remove a case to a secondary center in order to receive the benefit of the advice and treatment of specialists, the general practitioner would be afforded every opportunity of keeping in touch with the patient and of having him under his care again when discharged. It should be said that the secondary centers will consist of hospitals fully equipped and staffed by specialists, who if required may be called into consultation in the primary areas. In addition to these centers, the last link of the chain would be the teaching hospital. Indeed, the aim of the scheme is to link up these three factors so that they may work in unison and smoothly, as well as to relate them

to the preventive side of medicine. Furthermore, nursing, dental, maternity and other services will be brought into association. It is hoped by these means that all classes of medical men will enter into new relationship one to the other to the great advantage of individual and general health. The scope of medical service of the general practitioner will be greatly enlarged and the hope is expressed in the report that such duties as those of tuberculosis officer, venereal disease officer, school doctor, infant welfare doctor and even health officer may be entrusted to general practitioners, who will practice both preventive and curative medicine and who will serve in intermediary capacity between the people and specialist organizations in all cases.

Of course, while some parts of the scheme are visionary, other parts are practical, while all are possible, given time. The secondary centers cannot be established as yet on account of cost. The primary centers, which after all is the essential feature of the plan, are feasible at once. They can be opened at small cost, and what in existing circumstances is very important, by adding to the working power of the general practitioner will tend to relieve the strain on hospitals. As a matter of fact, it has been proved already that the essence of the plan is workable. It has been actually adopted and, to a very considerable extent, worked out by the public authorities and the medical profession in the county of Gloucestershire. This was due to the initiative and energy displayed by the medical officer of health of Gloucestershire, Dr. J. Middleton Martin, upon whose detailed scheme the proposals of the report were based. As said before, however, the interim Report of the Consultative Council of the British Ministry of Health is intended rather to point the way than as an exposition of the Council's conclusions. It is a document of surpassing interest not only to medical men, but to all those who concern themselves in public health matters and in the medicine of the future.

Etiology of Pellagra.—A paper was read on the etiology of pellagra, on May 14 last at a meeting of the Society of Tropical Medicine and Hygiene by Dr. G. G. Wood. Dr. Wood discussed the malady from the standpoint of a deficiency disease. The speaker fully indorsed the important conclusions of Joseph Goldberger as the result of observations based on (1) the dietetic origin of the disease; (2) its dependence on some undetermined error in diet, with a disproportionately high vegetable and a disproportionately low protein component derived from animal or leguminous sources; (3) the absence of pellagra among those consuming a mixed, well balanced and suitably varied diet. The infective origin of pellagra had at one time met with Wood's support until it was disproved by the experiments of Goldberger and his assistants. But in spite of the evidence against infection being very strong, the possibility of an infectious element playing, perhaps, a secondary but not less essential part could not be excluded. As for the distribution of pellagra in North Carolina it was pointed out that the disease was chiefly confined to the foothills of the high mountains bounding the western frontier, and that, as a rule, its incidence was much less along the Atlantic seaboard, while in the mountains themselves its occurrence was very rare. The dwellers in the mountains were described as being of the most degraded type of Anglo-Saxon known, and often living in most unsanitary and overcrowded huts, on a diet far from ideal. Yet the mountaineer did not suffer from the disease. His food consisted chiefly of corn ground whole at the local water mill and consumed before rancid decomposition of the germ could occur. On the other hand, the inhabitants of the foothills, workers in the local cotton mills, availed themselves of whatever was provided by the local merchant in the form of commercial corn-meal and patent wheat flour and adopted whatever means would curtail and facilitate the cooking process. In consequence, their food was composed of wheat-flour without bran, corn-meal milled without bran or germ, and a variety of chemical baking powders. It was among the consumers of this diet that pellagra prevailed. It was in consequence of Goldberger's influence and work that Wood was induced to regard pellagra from the analogy of beriberi as a deficiency disease. Wood, in fact, has been quite converted to Goldberger's theory as to the etiology of pellagra; that is, a food deficiency disease. In discussing the papers Dr. H. Manson-Bahr claimed that too great stress had been laid on the food deficiency theory as the main cause of the disease, and held that the theory of infectious origin had been effectually disproved. He maintained that food deficiency did not explain the occurrence of the sixty-five cases of pellagra among 70,000 German prisoners in Palestine and Egypt who had suffered no previous food shortage, many of them in good physical condition, not afflicted with dysentery or malaria. He asked why, if pellagra was due to a food deficiency, there had been no cases in Austria, where tuberculosis and rickets were so rife as the result of food shortage. He suggested as a possible explanation of the occurrence of pellagra in Egypt, especially among well-fed German prisoners, the action of a toxin peculiar to the endemic areas in Egypt effecting the endocrine glands and particularly the suprarenals, which, together with the sympathetic system, bore the brunt of the disease.

Lieut.-Colonel P. S. Lelean, R. A. M. C., supported food deficiency as the main cause. He commented on the conditions prevailing among Turkish prisoners from Gallipoli and Syria, and the absence of any source of infection in the towns of Syria, where the disease was unknown to Syrian civilian doctors. Among a batch of 4,000 prisoners who had experienced considerable food shortage there had been 279 cases of pellagra, which subsequently, under the influence of improved conditions in the prison camp, had dropped to twenty-seven. The striking contrast presented by the adjacent prison camps at Maadi, the one with 6,000 Turks and many cases of pellagra, the other with 2,000 German prisoners in good physical condition, could be accounted for only by a difference of diet. The occurrence at a subsequent date of sixty-five cases out of a total of 70,000 German prisoners, he contended could be explained on the score of a food deficiency by the

effect of heavy work when on a light diet calculated as sufficient to meet the ordinary demands of life, also by the failure of extra supplies which had at first been met through charitable agencies on behalf of prisoners, but had subsequently not been forthcoming in the later period of the war. The deviation of the biological protein of the light diet in response to the increased demands of heavy work, even if digestion and assimilation were correctly balanced, would, he considered, create a deficiency sufficient to account for the occurrence of pellagra.

2. Chronic Fatigue: Diet, Exercise, and Other Factors in Treatment.—John Bryant holds that the world is full of persons, mostly chronic invalids, who react excessively to sensory stimuli of both mental and physical origin. One obvious ultimate result of this continued overreaction to sensory stimuli is chronic fatigue. The patient will not recover until the chronic fatigue is relieved. In order to releve the chronic fatigue its cause must be attacked. In diet and exercise one has available two valuable but apparently too little appreciated active therapeutic procedures for an attack upon the problem of overreaction to sensory stimuli. He presents some details of the use of these two procedures.

6. Mastoidectomy Followed by Insanity.—Otto Glogau cites the case of a male patient, 29 years of age, whose history shows that he had always been well and had had no ear trouble until three months before examination by the writer. Paracentesis and later mastoidectomy were performed. The mastoid cavity proved to be totally destroyed and filled with pus and granulation tissue. The destruction reached up to the dura, which was exposed and found apparently normal. Pointing backward and downward there was an extensive perisinous abscess which reached from the sigmoid sinus toward the region of the bulb, where pus was constantly oozing alongside the sheath of the blood vessel. Conditions did not indicate sinus thrombosis. The cavity was not closed, but lightly packed, and regular dressing applied, which was changed every second day. On the fifth day the patient appeared somewhat stuporous toward evening, his pupils were widely dilated. During the night he became violent and jumped out of bed. Even after repeated hypodermic injections he had to be tied down to the bed. He then slept until morning, when he awoke with manifestations of great violence. The following summary of the findings is given: Dreamy states characterized by visual hallucinations; mastoiditis with involvement of the brain substance; clear intervals. A spinal fluid examination for cells was thought desirable. There was a strong suspicion of temporosphenoidal abscess. Further observation was thought necessary for the spread of signs and symptoms for the formation of laudable pus on the side of the involvement and an exploratory operation when this appeared. Spinal puncture showed the fluid to be under moderate pressure with a negative Wassermann. The cytology was normal and no bacteria were present. The fluid was clear and one plus for globulin. Gradually the patient became more and more sensible at night, and would talk less, falling asleep when exhausted. During the day he would even read the newspapers intelligently. He soon had perfect quiet. He was discharged from the hospital on the twenty-sixth day after the mastoid operation. Little was left that was pathological as far as the central nervous system was concerned. The deviation from the normal found in the right eye may have existed prior to the mastoid involvement. There was at this time no evidence of mental disease. The entire picture presented by the patient at the first examination is regarded as composed of two components: (1) A local edema of the temporosphenoidal lobe; (2) general toxic manifestations in the course of septic disease. With the recession of the focal edema most of the focal signs vanished. With the recession of the infection the infectious toxic signs vanished. From the study of this case the writer concludes that attacks of insanity following mastoidectomy, especially with exposure of sinus or dura, are of toxic origin. The contents of the hallucinations and delusions point also to a psychic cause, or rather susceptibility, which was founded on certain suppressed wishes and fears that occupied the patient's unconscious state previous to the operation. The otologist should therefore also have some understanding of the psychoanalytic side of the problem. Previous to any operation, especially on structures near the brain, an investigation of the patient's psychic status should be made. In case such postoperative attacks of insanity occur, mind rather than matter will then be regarded at fault. Disregard for the psychic aspect of the problem may give rise to the assumption of a temporosphenoidal abscess being the cause of these attacks of insanity, and may lead to an unnecessary exploration of the brain.

4. Measles: Brain Complications.—A. L. Skoog reports two cases of brain complications following measles. From his own cases and from a study of the cases reported by others he makes three groups of cases: The first group would include a certain minor number of cases in which the relationship of the measles would be merely incidental. The second group would include the secondary infections due to various organisms. The third group is a less certain one, owing to

the fact that the exact etiology of measles is as yet undetermined. The prognosis for these brain disorders depends on the brain tissue changes. The management and treatment depend on the lesions and the attendant deformities or deficiencies. Prophylaxis is of the first importance. Skoog has seen in his consulting practice and in the clinics of other neurologic consultants certain mild neurologic or mental cases that were difficult to catalogue. This includes some with the neurasthenic syndrome. They may have originated from troubles in the brain or meninges in the course of or following measles and other exanthems. Some of these neurologic disorders can be traced back to early childhood without knowing the exact etiology. He believes that at least a portion of these can be attributed to permanent pathologic residues caused by the toxin or virus of measles or from one of the complicating secondary infections.

7. Medical Progress in China Since the Republic. Wu Lien Teh.

6. Full-time Tubal Pregnancy. Cesarean Salpingectomy: Recovery.—R. Eccles Smith reports a case in which complete rupture of the tube did not take place. He admits that incomplete rupture of one or more of the coats may have occurred in the earlier months, followed by sufficient reinforcement by adhesions and localized protective peritonitis to thwart complete rupture, allowing a viable child to go to full term until delivered by surgical interference. He could find no similar case recorded in the literature. The patient was thirty-two years of age, a 3-para, the other children having been born naturally and without difficulty.

7. Medical Progress in China Since the Republic.—Wu Lien Teh says that in spite of the disturbed state of the country since the establishment of the Republic in 1911, the progress of medical and sanitary science has been very marked and steady, as shown by the readiness with which both the Central Government and the provincial authorities have established and supported hospitals and institutions of a sanitary nature, and by the increased interest shown by the general public in Western medicine, home cleanliness, and matters bearing a hygienic value. He discusses the subjects of the plague prevention service, interesting medical landmarks, the cooperation of Chinese and foreigners, and the pressing needs in the medical line. Among other interesting items mentioned is the appointment of a terminology committee, consisting of representatives of the Ministry of Educaton, National Medical Association, Medical and Pharmaceutical Society, Medical Missionary Association, and Kiangsu Educational Association, to determine the terms to be used throughout China. So far the complicated terms of anatomy have been finished and accepted by the government as official. The terms in bacteriology, chemistry, and physics have also been finished and are awaiting recognition.

2. A Collective Investigation of Ten Thousand Recruits with Doubtful Heart Conditions.—S. Russell Wells summarizes this fourth report as follows: Taking aortic regurgitation and mitral stenosis as the two typical valvular lesions which can be diagnosed with comparative certainty during life, the results of the present statistical inquiry lead to the following conclusions: (1) The most important etiological factor in the production of organic lesions of the heart valves in men between the ages of 18 and 41 is rheumatic fever. (2) Strain can independently produce aortic regurgitation. (3) While strain may be a cause of mitral stenosis, it is a much less important factor than in the production of aortic regurgitation. (4) There is a third agent giving rise to symptoms simulating influenza, which is an efficient cause of mitral stenosis, and can possibly affect the aortic valves as well, but is not nearly so likely to do so. Wells has been unable to find any statistical evidence that syphilis, scarlet fever, diphtheria, pneumonia, or gonorrhea, are causes of valvular lesions, nor can he find statistical evidence that a history of growing pains points to affections productive of valvular lesions. The same may be said, with slight reservations, of a history of rheumatism where there is no clear account of pain, swelling of the joints, fever, or confinement to bed. The evidence in favor of chorea as an efficient cause of mitral stenosis is strong, and he has found some, though not very striking, evidence in confirmation of the view that chorea and rheumatic fever are both manifestations of the activity of a common cause.

2. Relation of Deep Stricture of Large Caliber to Disease of the Lower Urinary Tract.—M. J. Latimer holds that many pathological conditions of the urethra and its adnexa are perpetuated by relatively slight coarctations of the canal. These coarctations act not only locally by producing irritation and preventing drainage, thereby perpetuating the infection, but they also produce reflex irritation of the deeper parts and also extension of the infection. Urethral strictures of large caliber can be diagnosed only by the expert use of the exploring bulb, the sound being worthless. Attempts at stretching in the majority of cases of this kind simply make a bad matter worse, urethrotomy being the only logical recourse. The degree of constriction of the canal is by no means a criterion of the necessity for operation. The important point to decide is not the degree of contraction but the extent to which the contraction modifies or perpetuates any present. To attempt to cure urethral, bladder, and prostatic disease in the presence of a stricture of large caliber which bears a definite relation to the symptoms, without removing the obstruction, is about as sensible as treating a case of conjunctivitis without removing the cinder which has induced it.

La Presse Médicale.

April 17, 1920, xxviii, 23.

Esthetic Grafting of the Scalp.—Passot describes his method, which has been greatly magnified in importance by the daily press, as follows: It is intended as a

cosmetic cure of baldness, and is comprised under cosmetic surgery in general. Passot has now 127 cases to report of cosmetic surgery of wrinkles, and has extended his work in other directions as the removal of disfiguring scars, but as for an esthetic cure of baldness that is at present largely in the air. The subject is not new, for German surgeons have practised it, at least in a small and tentative way. Thus small tufts have been grafted into the bald scalp, although without much success. The author would perform autoplastic grafting from a hairy to a bald area of the scalp. The temples and occiput are largely immune to baldness, and zones or bands can be switched from its bed in the hairy region to the normal junction of the frontal hair with the forehead. By proper care, the hair follicles being undisturbed, long hair may grow on the grafted area, and this may be brushed backward to cover the bald area. It is not suggested that more than two successive implantations be made for the remaining natural hair could hardly be made to spare further transplants. In certain cases a second flap may be placed behind the first. The optimum of interval is three weeks. The operation may be varied in several ways. The author has had six perfect results, and probably not a few failures, or at least he warns of various technical errors which invalidate the result. He used local anesthesia with great success, and states that hemorrhage was but trifling. After the first month there was enough hair on the grafted surface to conceal the incision, and after two or three months the hair was so long that it could readily be combed back to cover the remaining bald spot.

La Riforma Medica.

March 6, 1920, xxxvi, 10.

Lethargic Encephalitis and the Poliencephalitis of Influenza.—Zagari states that Camerarius of Tübingen was the first to describe under the name of sleeping sickness an affection in which somnolence and ptosis were present. This was in 1712, and the description differs from those of all other claimants for priority in the sure presence of ptosis and in the choice of the name. Catarrhal fever—the old name for influeza—with somnolence, was seen in epidemic incidence in Germany in 1745, in Lyons in 1800, in Milan in 1802, etc. There can therefore be little doubt as to the antiquity of both types of this affection, the primary and the secondary, or grippal form, whether these be the same or quite different in nature. We have next to ascertain whether the socalled "nona" of the nineties presented the ocular palsies. The most striking symptom of the cases of 1890 was the continuous sleep. The author is silent on the earlier cases, but in 1900 Bozzolo noted the implication of the cranial nerves, which, however, he ascribed wrongly to basilar meningitis. Apparently up to 1917 the nature of the ocular pareses and their constancy was far from recognized. When the disease appeared in mass incidence in Vienna in 1917 Economo noted at the outset the presence of eye symptoms. From that time the clinicians of the world were on the lookout for them. In regard to nosology the author makes three types based on pathological finds, to wit: the superior mesencephalic, characterized clinically by somnolence and motor paralyses of the upper cranial nerve, especially of the eye muscles; the inferior mesencephalic, in which the last six pairs of cranial nerves are involved, and an anomalous type which comprises all of the cases with polymorphous and atypical symptoms, and in which the entire neuraxis may be involved.

Hygiea.

April 15, 1920, lxxxii, 7.

Results of Operative Treatment of Hypernephroma.—Michaelsson refers to the dubious nature of these growths—whether of suprarenal or renal origin, the degree of malignancy, etc. The greatest collection of cases, by Paschen, shows that of 268 operative cases found in literature over 17 per cent had "permanently" recovered. The same author quotes 54 unpublished cases, apparently largely personal, which showed double this percentage of recovery. These statistics are not representative because the observation period of many was insufficient. By carefully editing this author's material from the viewpoint of a longer observation period there is no proof of extensive survival, and only a few cases show a long survival. It is known that late recurrence and late metastasis are both common in hypernephroma. Further, many patients being of advanced age may readily die of some intercurrent disease. Histological finds are of little service in fixing the degree of malignancy. The author cites a series of results of cases operated on at the Seraphiner Hospital of Stockholm during the period 1896-1915. At the request of Professor Rovsing, each case was carefully controlled for at least four years. In March, 1919, were living seven of the patients operated on from four to fifteen years before. Four patients died from the operation, which leaves twenty-six cases for statistics. Nine died of recurrence or metastases, and of this number three had survived longer than three years, while no less than ten had succumbed to intercurrent disease and of this number five had succumbed within eighteen months, thus vitiating the material for statistics. We can only say that of twenty-one operative cases seven recovered and nine died of recurrence, while five died of other diseases with a chance that the tumor would not have recurred within three years, at least.

Le Bulletin Médical.

April 10, 1920, xxxiv, 20.

Increasing Frequency of Chancroid.—Payenneville found that during 1919 in the general hospital at Rouen 235 primary venereal ulcers of all kinds had come under observation. Of this number sixty-one were examples of primary syphilis, 125 were chancroids and forty-nine were of the mixed type. This ratio of two to one in favor of the soft sore should be contrasted with the figures often encountered, in which the syphilitic initial sore outnumbers the chancroid by as much as four or five to one. In the army for the same period the ratio of the two was nearly equal, with only a slight advantage in favor of the chancroid. Even equality of incidence usually bespeaks a high frequency for chancroid, and hence two to one in favor of the latter means a specially high incidence. It has long been known that in times of great commingling of men, as during army mobilizations, expositions, etc., a notable frequency in the incidence of chancroid is noticeable; and conversely when the population is stationary and in equilibrium this frequency declines. With increased frequency in general the increase in the incidence of mixed chancre should be noticeable. The author is inclined to accuse defective laboratory technique as a factor in the establishment of false statistics. For example, many clinical chancroids may be found to contain the treponema. These are technically mixed chancres, although in the past they have counted as simple sores. Again, a chancroid may, if examined later, be found to be a mixed lesion. The author would therefore always take a Wassermann reaction in chancroid. He has shown by attention to details of technique that mixed chancre, far from being a curiosity, is relatively common. Laboratory follow-up activities are necessary for arriving at the actual frequency of chancroids.

The Fleiss Periodicity Theory.—Fleiss, discoverer of the nasal genital area and promulgator of the twenty-three and twenty-eight day theory of periodicity of certain events, has added data to his original material published in book form some years ago. The menstrual periodicity of the mother may be handed down to the offspring, so that on certain days certain operations like tonsillectomy are more apt to be followed by primary or secondary hemorrhage. Cerebral apoplexy and other suddenly fatal affections may occur on the periodic days. In general the day of death, the day on which one is attacked by a given disease, the day in which labor begins, etc., may show in a given family strain a close correspondence. The day of birth, of the menstrual period, etc., correspond to the periodic days, and it seems evident that on these days the resistance to disease is lowered.—*Schweizerische medizinische Wochenschrift.*

Book Reviews.

HANDBOOK OF DISEASES OF THE RECTUM. By LOUIS J. HIRSCHMAN, M.D., F.A.C.S., Vice-Chairman, Section on Gastroenterology and Proctology, A.M.A.; ex-president American Proctologic Society; Professor of Proctology, Detroit College of Medicine; Proctologist Harper Hospital; Major, M.C., U. S. A. (Honorably Discharged), Detroit, U. S. A. With 223 illustrations, mostly original, and four colored plates. Third edition, revised and rewritten. St. Louis: C. V. Mosby Company, 1920.

THE new edition of this excellent work has been improved by the addition of a number of illustrations further elucidating the text which, thanks to the author's pleasing literary style, is in itself very clear and understandable. Any one studying this book comes as near to a clinical demonstration as is possible without the patient actually on the table. Dr. Hirschman is extremely partial to local anesthesia and asserts that fully 75 per cent. of all rectal and anal diseases are amenable to treatment without resort to general anesthesia. The reviewer lays no claim to anything approaching the author's experience in this field, yet he cannot but think that Dr. Hirschman's success with local anesthesia in this sensitive portion of the body is due very largely to his personal skill and that the majority of operators—certainly the majority of patients—will not accept this estimate of the wide applicability of the use of quinine and urea hydrochloride in anorectal surgery.

DISEASES OF THE CHEST AND THE PRINCIPLES OF PHYSICAL DIAGNOSIS. By GEORGE WILLIAM NORRIS, M.D., Assistant Professor of Medicine in the University of Pennsylvania; Visiting Physician to the Pennsylvania Hospital; Assistant Visiting Physician to the University Hospital; lately Colonel, M.C., U. S. Army; and HENRY R. M. LANDIS, M.D., Assistant Professor of Medicine in the University of Pennsylvania; Director of the Clinical and Sociological Departments of the Henry Phipps Institute of the University of Pennsylvania; Visiting Physician to the White Haven Sanatorium, with a chapter on the Electrocardiograph in Heart Disease, by EDWARD B. KRUMBHAAR, Ph.D., M.D., Assistant Professor of Research Medicine in the University of Pennsylvania. Second edition, revised. Philadelphia and London: W. B. Saunders Company, 1920.

THOSE familiar with the first edition of this work will welcome the appearance of a new and improved one. Among the additional subjects included are influenza, spirochetal bronchitis, streptococcal empyema, pneumopericardium, and calcification of the lungs. All the features that made the first edition such a valuable work are retained in this. Especially to be commended are the discussions of the acoustics of the chest, and above all the numerous and helpful illustrations; there are over four hundred of the latter, some of them colored, and most of them very apt and beautifully executed; they add enormously to the value of the work as a guide to the student and practitioner. In the sections on the various thoracic diseases chapters are devoted to the morbid anatomy and etiology, in addition to the symptoms and physical signs, but the treatment is not discussed. With this limitation, which is not made clear in the title, the book is to be most heartily commended to the study of every general practitioner, so large a part of whose practice has to do with diseases of the chest.

MANUAL OF PSYCHIATRY. Edited by AARON J. ROSANOFF, M.D., Clinical Director, Kings Park State Hospital, New York; Lieutenant-Colonel, Officers' Section, Medical Reserve Corps, U. S. Army. Fifth Edition, Revised and Enlarged. New York: John Wiley and Sons, Inc., 1920.

THIS handy little volume is growing somewhat in bulk with every edition, but the increment always contains so much of value that no possible objection can be found to it. Even this edition, with its chapters on psychoanalysis, forensic psychiatry, and its remarkably complete section devoted to various kinds of examinations, does not exceed in bulk one of De Morgan's novels. One might perhaps wish for more clinical material in this almost wholly didactic volume, for we do not believe psychiatry can be mastered in such a manner.

However, as a manual for the teacher of psychiatry to lecture from, a guide to which the student of psychiatry can turn while studying his patients and a ready reference book for the general practitioner, it is difficult to surpass. We know of only two other books of similar scope in English which are in its class. Rosanoff gives much credit to his chief collaborator, J. Rogues de Fursac, whose name, it will be remembered, formerly appeared on the title page, and also to H. L. Hollingworth, Mary C. Jarrett, and Clarence A. Neymann. Dr. Hollingworth's contributions are especially valuable.

SYPHILIS, a Treatise on Etiology, Pathology, Diagnosis, Prognosis, Prophylaxis, and Treatment. By HENRY H. HAZEN, A.B., M.D., Professor of Dermatology and Syphilology, Medical Department of Georgetown University; Professor of Dermatology and Syphilology, Medical Department of Howard University; Member of American Dermatological Association and National Association for Control of Syphilis; Visiting Dermatologist and Syphilologist to Georgetown University Hospital, Freedmen's Hospital, Washington Asylum Hospital, and Woman's Evening Clinic; Author of "Diseases of the Skin," "Cancer of the Skin," etc. With 160 Illustrations, including 16 Figures in Colors. St. Louis: C. V. Mosby Company, 1919.

IN the past few years a multiude of volumes on Syphilis have been presented to the profession. The greater part of these deal with the treatment of the malady with particular reference to intravenous injection of the arsenicals. The excellent work now under consideration deals thoroughly and concisely with every problem confronting the syphilographer. The author has induced many eminent men to write special chapters. Among them are Reasoner, Fowler, Dunlop, Lind, Hough, Dabney, Greene, Craig, Schamberg, Van Sweringen, and Reede. These chapters are so skilfully written and interpolated that they do not jar the reader, but materially balance and symmetrize the book. The sections on Syphilis of the Nervous System (by John E. Lind) and Congenital Syphilis are especially praiseworthy; as is the short chapter of five pages on "Prognosis" wherein the author's sane pessimism may halt many enthusiasts. Although a correct appreciation of the book requires its reading throughout, yet its sequential arrangement of subjects adds to its value as a volume for reference. The opening sentence of the preface may be paraphrased: "At the present time there exists no (other) small book that covers the whole field of syphilis in an authoritative way."

THE PRACTITIONER'S MANUAL OF VENEREAL DISEASES, with Modern Methods of Diagnosis and Treatment. By A. C. MAGIAN, M.D., Ancien Elève de l'Hôpital St. Louis, Paris; Hon. Surgeon Manchester French Hospital; Hon. Surgeon Wood Street Clinic for Genito-urinary Diseases. St. Louis: C. V. Mosby Company, 1919.

IT is doubtful whether or not the author has accomplished his aim "of giving a concise outline of the diagnosis, symptoms, and treatment of venereal diseases as we are acquainted with them to-day." He hopes to furnish the general practitioner with a manual which will not leave him in a mental fog, rarely dispersed without a great deal of outside assistance. In his endeavors to accomplish the first aim he thwarts his second. Gonorrhea is disposed of in fifty pages; gonorrhea in the female in four and one-half pages. He loses his opportunity to teach the general practitioner to think logically and correctly. Epididymitis is referred to as "inflammation of the testicles." The great biological principles of disease go unheeded in such statements as "To destroy the gonococcus we must use injections." . . . The latter three-fifths of the book deals with syphilis in all its phases and constitutes by far the more valuable portion of the volume. The chapter on the history of syphilis is clear and well written. The illustrations of Frenkel's methods of teaching the ataxic to walk are well chosen and of value.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held February 5, 1920.

THE PRESIDENT, DR. GEORGE DAVID STEWART, IN THE CHAIR.

THE program of the evening was arranged in cooperation with the Association for the Prevention and Relief of Heart Disease.

Extent of Cardiac Disease Among Children of School Age in New York City.—Dr. J. L. BLUMENTHAL of the New York City Department of Health, representing Dr. S. Josephine Baker, spoke on this subject. He stated that a great deal of attention had not been paid to cardiac disease in school children heretofore, because they had not had an association of this kind to get together and discuss these cases and the methods of affording relief. In the New York schools the medical inspectors were making examinations and tabulating the results, which showed that the incidence of heart disease among school children was from 1.4 to 1.9 per cent. These figures appeared so constantly that he felt they expressed about the true extent of cardiac disease among school children. Recently a complaint had come to them from clinics that they were sending too many cases of cardiac disease which were found not to be cardiac disease when they arrived at the clinics. There was an excuse for that. They felt that they would rather send to the man who was going to make the diagnosis, not only actual cases of cardiac disease, but cases in which there was any possibility of a cardiac condition, and permit him to make the diagnosis. The same was true of hypertrophied tonsils and other conditions. In the Health Department they did not make diagnoses, for they did not have a proper room in which to make examinations and they could not strip the children. They had devised a plan of having the boys open their shirts for these examinations, but all they did was to pick out the suspicious cases, and they expected the physician not only to make the diagnosis but to care for the case. In examining the girls they did not open the waist unless a parent was present. The proposition had been made that the Department of Health should establish cardiac classes. While there were many good points in cardiac classes, they in the Health Department felt that the difficulties in the way of establishing such classes far outweighed the advantages and that at the present time such a plan was not feasible. A teacher was needed for every twenty-five cardiac children and each teacher would have to have four or five grades in her class. They had felt that the matter of physical exercise was the only reason why such classes might be an advantage. Furthermore, such classes would be a large item of expense and they felt that this money might better be expended in regulating conditions in the home, as, for instance, if a family was living on the top floor and it was found that the stairs were too much of a strain for the child, it was better to assist that family to move downstairs. In the matter of exercise, a letter to the teacher would excuse the child from gymnastics, and the teachers would see that such a child used the front stairs in fire drill. Then there were psychological reasons why it was better not to put girls ten or twelve years of age into cardiac classes where they were constantly reminded that they had heart disease and came to think of themselves as invalids. Some who had made tests in children knew that a heart even with an organic lesion was not affected by exercise to the extent that some believed. So owing to the many disadvantages of cardiac classes they had decided that they should not be established. They wished, however, to make an appeal to private physicians and dispensaries to treat all children that were sent to them by the Department of Health and to send the diagnosis to the Health Department. Dr. Blumenthal said he had made a study of conditions other than heart disease and found that private physicians were low in the number of physical defects that they found in school children. There was a provision of the Sanitary Regulations that permitted private physicians to examine school children when the parents so desired. Private physicians had found only 2.3 per cent. with defective vision, whereas the inspectors of the Department of Health had found in the same age group 9.4; private physicians found 5.7 per cent. with nasal breathing, compared with 10.1 per cent. found by the inspectors; private physicians found hypertrophied tonsils in 12.1 per cent., while inspectors found this defect in 3.5 per cent. Undernutrition was found in only 5.7 per cent. by private physicians, as against 14.2 per cent. of those examined by inspectors. In cardiac disease the percentage was about the same whether the children were examined by private physicians or inspectors. On the other hand, private physicians found twice as many pulmonic defects as did the inspectors. In examining teeth private physicians found 19 per cent. defective, while the inspectors of the Health Department found defective teeth in 65 per cent. That was because the private physician did not call the attention of the parents to the teeth because they still felt that the primary teeth need not be cared for by the dentist. An association of this kind could be useful and should be encouraged because there was a real necessity for their work. He hoped that some time later the subject could be threshed out and the public invited to learn about cardiac conditions in school children and among children in general.

Incidence of Heart Disease in Adults.—Mr. LOUIS I. DUBLIN, statistician of the Metropolitan Life Insurance Company, spoke on this subject by invitation. He said that at the present time there were two outstanding public health problems about equally important, tuberculosis and heart disease. They both caused in the United States about an equal amount of sickness and death, there being about 150,000 deaths annually due to each of these two causes. From the point of view of illness there were perhaps 2,000,000 sufficiently impaired in health by heart disease to seriously interfere with their functioning in everyday life. The field of tuberculosis had been pretty thoroughly exploited for a period of over thirty years and thousands of physicians had been trained to care for the tuberculous. Institutions had been established for their care and a national program had been developed, whereas for the solution of the other problem, equally important, scarcely anything had been done. The death rate from tuberculosis had been reduced probably 50 per cent., but there was no evidence that the death rate from heart disease had been reduced at all. In fact, there were very excellent figures for the registration area which would indicate that there was a rise in the mortality from heart affections. It could be said then that there was a real need for an organization to develop a program and interest throughout the country in this problem. We had in heart disease a problem exactly similar to that presented by tuberculosis, the surface of which as yet had scarcely been scratched. Evidences in support of these striking statements might be divided into three heads: First, sickness rate; second, lethal rate from sickness, and, third, death rate from heart disease. The evidence as to the incidence of heart disease came from a number of sources, among these the material of life insurance companies, which make millions of examinations yearly. A certain proportion of applicants for insurance were regularly rejected because of heart lesions sufficiently important to justify the expectation that they would not show a longevity in excess of thirty or forty years. The life expectation to-day was fully one-third better than it was seventy years ago, yet that did not apply to cardiac disease, and 2 per cent. of the persons examined were rejected for heart lesions. Examinations were made by physicians in large industrial establishments and they concurred fully with what the medical examiners of life insurance companies had found. The United States Public Health Service had examined many thousands of individuals and had found 2 per cent. showing serious organic heart lesions. Those were also the findings of Dr. Robert Wilson of Cincinnati and of Dr. Harris in his examination of the food handlers of New York. In the draft examinations 2.16 per cent. of the men in the prime of life were rejected because of heart impairment. Putting all these figures together, there was no escape from the fact that among men from 25 to 30 or 31 years of age at least 2 per cent. suffered from sufficient impairment of the heart to markedly curtail their longevity. One life insurance company had

kept records for eighteen years of the examinations that had that had shown mitral regurgitation, and had accepted such applicants for insurance on a large extra premium. Last year they made a careful study of these records by the best actuarial methods and found that this group of some six thousand persons had a mortality of from 50 to 100 per cent. in excess of other individuals of corresponding age. The experience of the New York Life Insurance Company showed the same results. It might then be said that persons with moderate heart impairment, justifying insurance at an increased premium, had a mortality of 50 per cent. more in the younger group and 100 per cent. more in the older group, that was between the ages of 42 and 45 years, than that of the normal individual. For other heart defects such as aortic stenosis and aortic regurgitation the mortality was so much greater that they had quit that type of business. There was a large number of deaths then from organic heart disease even at the earlier ages, and at the older ages heart disease was the first of all causes of death. Taking all ages together in the registration area, heart disease was the leading cause of death, having exceeded tuberculosis. In the years just preceding the epidemic of influenza there were 150,000 deaths a year from this cause in continental United States. The rate had been rising steadily during the last decade, there being a drop last year for the first time. Beginning with 1911, the rate of 241.7 had continued with slight change until 1919, while during that period the mortality from tuberculosis had dropped 30 per cent., but in 1919 the death rate from heart disease dropped to 111.7, an unprecedented drop of 130 points. During the first nine months of 1919 the rate was practically the same as for 1918, but during the last three months there had occurred this extraordinary decrease in the number of deaths from heart disease. However, for the last three months of 1918 the death rate in America was the worst on record, there being an increase of 16 per cent. in the mortality. That same condition appeared in the figures for New York City and for New York State. This decrease in the death rate from heart disease was coincident with the epidemic of influenza. The 16 per cent. increased death rate during this period probably included a large number of those suffering from heart disease who would otherwise have died six months later. Mr. Dublin said he merely suggested that as a possible explanation of the fall in the mortality from heart disease in 1919 and did not know whether it had merit or not. The colored element, the essayist stated, suffered twice as much as the white from heart disease. The mortality from heart disease was considerable even in youth. Under twenty-five years of age there were more deaths from heart disease than from typhoid fever, and from the ages of 15 to 24 years the mortality from heart disease was higher than from lobar pneumonia. That continued up to the age of 35 years. From the ages of 35 to 44 there were as many deaths from heart disease as from Bright's disease, and after the age of 45 there were more deaths from heart disease than from any other condition. Was that a problem worthy of attention? There were 2,000,000 persons with serious heart impairment in America and there were 150,000 passing out each year, that meant that the ratio of deaths to those having heart lesions was as one to fifteen. In other words, the average case of impaired heart lingered along for fifteen years, and he was speaking only of those heart conditions sufficiently serious to interfere with a man's ability to do his work and which ultimately killed him.

Sanatoria for Cardiacs.—Dr. CHARLES HENDEE SMITH read this paper, in which he said that it would be granted by any one who had given thought to the treatment of cardiac disease that the mechanism for caring for this class of patients was far from satisfactory. There was no such complete program such as they had for the care of tuberculosis and syphilis. When the cardiac patient came to the hospital he was patched up and went back to work; sooner or later he came back with a breakdown, and finally came a hospital admission which solved the problem for that patient only. Cardiac classes had been formed and these did a great deal to avert the final breakdown by regulating the general activities, suggesting the mode of life, and detecting early symptoms of a breakdown. Several homes now took selected cases of cardiac disease, but these were few in number. The Burke Foundation took those over twelve years of age and the Pelham home took girls from six to sixteen years of age. There were, in addition, a number of other institutions who took this class of patients, but they were all too few. There was no place for a boy over sixteen years of age. A convalescent home put the heart patient further from a breakdown than did the hospital as at present constituted. The stay to be productive of real good must be two or three months and sometimes longer. In the institutions caring for cardiac cases there was room for a great deal of improvement, and lack of funds had made the care far from satisfactory. Patients convalescent from heart disease were not convalescent in the sense that they were convalescent from pneumonia, typhoid fever, or other acute conditions. Therefore it was necessary to outline a somewhat different plan for their care. There was an analogy between cardiac disease and tuberculosis. The keynote in the care of the tuberculous patient was that as soon as the diagnosis was made he was sent away to stay for three to six months, or even for one or two years, until his disease was arrested, and he must lead a careful life afterward. While in the sanatorium he was taught the laws of hygiene and advised as to the proper conduct of his life after he left the institution. He got both the cure and the education. Where did the cardiac get these things? There was no doubt he needed them both. The program was a little different from that employed in tuberculosis, but there were many points in common. The cardiac required rest and more rest, fresh air, good food, and graduated exercise. The cardiac even more than the tuberculous patient needed to be taught how to regulate his future life. It was better to have some sort of sanatorium as a basis for the treatment of cardiac disease and for putting the patient in possession of the knowledge of how to direct the rest of his life. For the sanatorium treatment of the cardiac a general plan might be outlined. Under such a plan the first essential was that the patient must be kept long enough to accomplish some good; probably the average stage should be six months or more. As yet they did not know a great deal in reference to the employment of graduated exercises; they did not know how much exercise was right for different types of heart disease. Nutrition was very important because the nutrition of the heart muscles increased with the general nutrition of the patient. In children rest and good food with attention to the way in which it was eaten was a very important asset in the treatment of cardiac disease. It was only by obeying every law of health that one could hope for improvement in this class of cases. These patients should be taught to enjoy a clean body, clean teeth, and clean clothes. Dr. Smith stated that they had been sending each year about thirty patients to the Pelham home, most of whom were quite well compensated. Children who were in danger of decompensation should be cared for in wards, and one long hospital stay was better than several short ones. About 80 per cent. of the children sent were undernourished. Children who did not do well were not kept. The average stay was 2½ months; that included all, and some had to be sent home very quickly on account of homesickness. The fact that homesickness occurred was probably owing to some error in technique; they ought to know how to make these children happy. The improvement in the condition of the girls was unbelievable. Gain in weight was significant. Nine out of ten times they succeeded in making the cardiac gain in weight and the heart condition improved at the same time. They had divided these children into age groups, and found that the average gain in weight for those under twelve years was six or seven ounces a week, or about twenty pounds a year, which was four times the average gain in weight for children of this age. The girls over twelve years of age gained thirteen or fourteen ounces a week, which was also four times the expected gain for those ages. This was true of all classes of cardiac cases, just as true of those with heart symptoms as of those without heart symptoms. This gain in weight was followed by improvement in heart action and general condition, and it gave the patient a better chance for the future. In the treatment of cardiac disease attention must be

given to the removal of other physical defects, particularly those associated with the portals of entry of infection. Every institution for the treatment of cardiac disease in children should have associated with it a good dentist and a good nose and throat specialist, and there should also be facilities for the treatment of syphilis. Amusements should be provided, and if an institution were under State control educational facilities also should be provided. Vocational training might well have a place especially as many adults might have to change their occupations. The cottage system seemed to offer advantages, as it could stimulate home conditions and the girls and women might do a share of the work. Under a cottage system patients should be grouped according to age, sex, and the severity of the condition. A separate place should be provided for girls with vaginitis. An infirmary should be attached to every institution, for even though it took only incipient cases it should be prepared to care for any case of decompensation that might occur. Provision should also be made for the care of hopeless cases, as many of these patients lived long after they were totally incapacitated for work.

Syphilitic Cardiovascular Diseases in the Army.—Dr. LEWIS A. CONNER said he had not expected to find his name down on the program for a paper and he had only a few words to say about the subject, and that only because as the subject of cardiovascular disease was considered by this organization the question of prevention was the thing that loomed large. That was what they were all thinking about and trying to make headway with. There was one particular matter in connection with syphilitic disease of the heart and arteries in the army which seemed to point in some way to this question of prevention. The point which he wished especially to bring out was the apparent extraordinary rariety of specific cardiovascular disease in the army. After the men were sent from the draft boards to the camps they were all subjected to a very thorough special cardiac examination, as they were also to a thorough examination for the purpose of detecting tuberculosis. Both of these examinations were made by men chosen and trained in the army schools, so that they were thoroughly qualified to do this work and there was every reason to believe that the work was carefully done. Among one million men so examined there were over 11,000 rejected for cardiovascular disease, and among these 11,000 cases only 20 cases of thoracic aneurism were found. For the other type of luetic disease—aortic insufficiency—it was not possible to give figures, as the luetic cases were not separated from those of the rheumatic type; but a personal investigation of this point at many camps while the examinations were going on showed that, whereas cases of rheumatic aortic insufficiency were not uncommonly found, those due to syphilis were extremely rare. In other words, in this group of men between the ages of 21 and 35 years evidences of syphilitic cardiovascular disease had been conspicuously rare in spite of the fact that a considerable proportion of the men, especially among the negro troops, were known to have had lues. These facts seemed to confirm the belief that the period of latency in syphilitic cardiovascular diseases was very long and that clinical manifestations of vascular involvement usually appear only ten, fifteen or twenty years after infection. The question as to how this fact could be utilized to prevent involvement of the vascular system was the one that concerned them. It seemed to him that it offered encouragement for the belief that, with the modern methods of diagnosis and the prompt thorough and continuous treatment of syphilis in its earlier stages, much might be done to prevent these grave, late manifestations.

Sanitarium Treatment of Cardiac Cases.—Dr. T. B. BARRINGER, Jr., spoke on this phase of the subject. He said he did not think the parallel between the sanitarium treatment of tuberculosis and that of heart disease was at all a close one. There was a small group of cardiacs composed of children and adults which was suitable for intelligent sanitarium treatment. The members of this group had had diseased hearts for varying lengths of time and were recovering from a reinfection of the heart. The average member of this group did not need sanitarium treatment longer than from four to eight weeks. If, after four weeks, any patient showed that his heart's reserve power had not been improved or improved but slightly by correct hygienic conditions and graduated exercise, he should be discharged to home or an institution for chronic invalids to make room for a patient who can be improved. Rest was *not* the important part of sanitarium treatment of cardiacs. These patients were presumably free from active infection and they need exercise graduated according to the powers of their respective hearts. His experience with exercise in these patients was quite in accord with Dr. Brushs'. Also too much empñasis should not be laid upon the nutrition of these patients, children or adults. The toxemia incident to infection and the presence of foci of infection would cause these patients to lose weight. Just as soon as these conditions no longer existed a child's weight would increase even under hygienic conditions but moderately correct. Increase in the reserve power of a child's heart did not necessarily go parallel with an increase in weight any more than it did in an adult. The small group of patients described above was most suitable for sanitarium treatment. There was another group of children and adults whose hearts were hopelessly crippled, with little or no cardiac reserve power, who should be sent to sanitarium only for humanitarian reasons and because their families could not look after them. The great bulk of cardiac patients was composed of patients who had but one heart infection and these were best taken care of in cardiac clinics.

Dr. T. STUART HART said he thought all present had been impressed by what the first two speakers had said in regard to the size of this problem. Even if one had thought it over it came home to him with new force that we had in this country 2,000,000 cardiacs and that there were among school children such a very large number classified definitely as cardiacs. We would, of course, have to take care of these people with heart trouble. The greatest problem, however, was how we were going to prevent a large proportion of these 2,000,000 from becoming cardiac cases. Dr. Smith had presented a definite program for handling the problem, and while listening to him it had occurred to him that it might be a good idea to make a study of the relation of the tonsil to cardiac disease. If any one present had access to the records in a large number of cases it might be possible to get accurate statistics as to what tonsillectomy had accomplished in the prevention of heart disease. This could be done by taking two groups of cases, one in which tonsillectomy had been done and a group in which tonsillectomy never had been done and studying the incidence of heart disease in these two groups. The other part of the program seemed rather appalling when one thought of providing sanatorial care for 2,000,000 patients, but he did not think they need worry about this when they knew what had been accomplished in the care of the tuberculous. The interest in cardiacs was quite as widespread as in the tuberculous; the only trouble was that people had not gotten together and taken hold of the problem as they had done in regard to the care of tuberculosis patients. If they could get people to thinking he had not a shadow of doubt that the same amounts of money would be provided for the care of cardiacs as had been for the tuberculous. That time was bound to come and was not a long way off. When we talked about heart disease most of us naturally thought of valvular disease, but practically every damage to the valves involved also damage to the myocardium, and that was one of the reasons why reinfection was so serious and important a matter. The importance of infection in relation to cardiac defects was recognized by the War Department. Men were accepted with systolic murmur at the apex without hypertrophy or evidence of insufficiency, *provided* they did not have a previous history of infection that might be pointed to as the cause of the lesion which gave these physical signs. For instance, a man giving a history of tonsillitis or acute rheumatic fever was not accepted, not because his heart was so much damaged at the present time, but because they knew that when a man had once had rheumatism he was more likely to have another attack, and that another attack would probably affect his heart and make him inefficient as a soldier. That common type of heart irregularity known as auricular fibrillation was one of the evidences of

myocardial damage which occurred not as a rule at the time of the first attack of rheumatism, but one which might manifest itself anywhere from three to twenty years afterward. If one took a group of these auricular fibrillations among rheumatics he would find that the auricular fibrillation appeared on the average from ten to fifteen years after the original heart damage, though it was sometimes the first patent evidence of myocardial change. That being true it gave them a considerable period in which to care for and treat these individuals and to guard against physical and emotional stress and secondary infections, thus avoiding cardiac insufficiency. The significance of secondary infections was brought out time and time again in pneumonia, for example, when the heart with a valvular lesion that had been in existence for twenty-five years manifested itself as a cardiac insufficiency during an attack of pneumonia. There were three points to be emphasized: First, and above all, we must try to prevent some of these 2,000,000 persons with impaired hearts from becoming cardiacs. Second, we must guard those who had valvular lesions or myocardial lesions from severe physical exercise and emotional stress that might cause an acute dilatation and cardiac insufficiency. Third, we must work with those who were working against infection of all kinds in order that the group in which we were interested might not become infected and develop a cardiac insufficiency because of a reinfection.

Dr. LOUIS FAUGERES BISHOP said that certain points had been brought out by the speakers that needed emphasis and they needed to have opinions expressed that would aid them in deciding certain questions. Dr. Blumenthal, in stating that he did not believe they needed separate school classes for cardiac children, and with that statement he was fully in accord. If the cardiac child were separated from other children it made him self conscious and the fact that his heart made him a mark of attention had a very bad psychological effect on him. These children did better if they grew up with a group of healthy children. A teacher who had one or two cardiac children in her class usually gave such children special attention and they got better care than though one teacher had a great number of cardiac children to look after. He was glad Dr. Blumenthal had spoken of exercise and believed a mistake had been made in limiting the exercise of children with slightly defective hearts. When there was acute inflammation of the heart it was all right to limit exercise, but he felt that children, with their small, light bodies and agility, did not do their hearts much damage by exercise and they did better if they had their liberty. For instance, sinus arrhythmia was a condition that did not indicate any damage to the heart, and the child with this condition had better be put back in the healthy group at once. Dr. Dublin's statistics were very interesting and very reliable. He had every confidence in the observations of life insurance companies; such observations were very carefully made because they meant money and their statistics were the best thing we had for our guide in medical matters. Improvement in diagnosis might account for an apparent increase in the incidence of heart disease. Modern cardiology started only fifteen years ago and had changed their views of cardiac disease, and led to the recognition of many cases that formerly might have passed unrecognized. The old-fashioned family doctor used to tell the patient with cardiac symptoms that his stomach was the source of the trouble, because to tell such an individual that he had heart disease was to give him his death warrant. That was no longer done. In the care of cardiac patients the most important point was to do, as they had done for some years in Europe, insist that the cardiac patient take a course of treatment, take some cure, every year, which meant in reality a glorified vacation. The patient thus took care of his disease and got a fresh start. There should be special hospitals for heart cases, such as they had in London, because, as they all knew, the heart patients in the big general hospitals did not get a square deal. The psychology in dealing with heart cases was all wrong. Everybody regarded the heart patient as hopeless, and he or she was shown as a curiosity to every student who came along, whereas the heart sanatorium should be founded on the idea of getting well. Those suffering from other conditions went to a sanatorium with the idea of getting well, and he felt convinced that a heart hospital founded on the right psychology would be a wonderful thing.

Dr. ROBERT H. HALSEY said he wished to bring into the discussion one thought, and to emphasize it, since it was a factor in relation to the relief and prevention of heart disease, which the society could help to disseminate, and that was a proper psychological point of view toward heart disease. Every speaker had brought out to-night, either by direct statement or by implication, that heart disease was hopeless as to life and the patient should be kept ignorant of his condition. It seemed, if the physician could be of assistance to the patient with cardiac disease, it was in educating himself first to recognize the true extent of the damage to the heart of the patient, then present the proper picture to the patient, to help him meet his living conditions without damaging his heart. Every child should be taught ways in which he can get enjoyment out of life without injuring his heart, and that heart disease is not a stigma, the knowledge of which is to be kept from his next-door neighbor; that he should avoid overtaxing his heart, just as a child with a leg damaged by anterior poliomyelitis, but not with a hopeless point of view as so many have been accustomed to regard it. The patient can cooperate with knowledge, and the physician should not let him take the chances of ignorance.

Stated Meeting, Held March 4, 1920.

THE PRESIDENT, DR. GEORGE D. STEWART, IN THE CHAIR.

THE program of the evening was contributed by the Section on Otology.

The Deafened Man's Needs and What the Physician Should Do for Him.—Dr. WENDELL C. PHILLIPS presented this paper, in which he discussed the problem of the deaf from the standpoints of congenital and acquired deafness. He said he did this because the testimony of deafened people and of social workers had shown that these two types of deafness must be handled separately. Their efforts in dealing with congenital deafness must begin in childhood. Commonly congenital deafness resulted from suppurations following diphtheria, scarlet fever, or measles. A chronic purulent otitis media frequently followed an acute mastoiditis which should have been operated upon. All cases of persistent discharge from the ear should be detected and placed under treatment. It was now known that the foundation of a chronic ear condition was usually laid in childhood or early adult life. This fact should be brought to the attention of the family physician, parents, and health authorities. It was a matter worthy of the attention of the State Department of Health which should make provision for the examination of the ears of children in the public schools, and should organize clinics for those children who had ear conditions needing treatment. In this work they should receive the cooperation of institutions devoted to ear, nose, and throat work. This was one of the departments of endeavor which the American Red Cross was going to undertake by the dissemination of literature on the prevention of deafness. Glasgow was the only city in which systematic and organized work was being done in looking after the ears of the children in the public schools until recently, when Dr. Franklin W. Bach, of Rochester, had carried out a somewhat similar work among the public school children of Rochester, N. Y., with surprisingly satisfactory results. The otologists of this country, together with the League for the Hard of Hearing, should grapple with this problem of diseases of the ear. There were many whose hearing might be improved by the removal of tissue from the nose and throat, together with improvement of the general health. The otologist should not only furnish treatment as an otologist, but should treat the patient as a client, doing all he could to insure his comfort and warning him against the charlatan who could do him no good and who would deplete his finances. The physician should also warn the deafened against his arch enemies, hypersensitiveness and despondency. He should be urged to employ aids to hearing, to engage in conversation with his friends, and

to make every effort to readjust himself and to reconstruct his life. He would receive such an impetus by meeting and learning from others who had had a similar experience. This ideal would be brought about by organized effort largely along social and economic lines. The League for the Hard of Hearing had accomplished wonderful results, and of all the things it had done, lip reading offered the greatest hope. All otologists who were long in practice were called upon to say the final word as to whether any hope of a restoration of hearing remained, and clear duty called upon them to tell the truth. But the bald fact of permanent deafness without telling the afflicted person of the chances of readjustment smacked of cruelty. Lip reading went far to replace loss of hearing, and there were a number of ways in which the deafened could readjust their lives. One thing to tell the patient to do was to go to Miss Peck and listen to her advice, and to hear what had been done for those worse off than himself.

The Deaf Child.—Dr. MAX A. GOLDSTEIN of St. Louis, founder of the Central Institute for the Deaf, made this address, in which he said the League for the Hard of Hearing, not only in this city, but throughout the land, was worthy of a boost. The problem of the deaf was one which the doctors knew little or nothing about, but something about which they should know a great deal, for it was part of the responsibility they assumed in their professional career. One could interest a body of doctors in a new operation, a new point in pathology, or a new treatment for disease, but his experience had taught him that it was a very difficult thing to interest his colleagues in otology in the problems of the deaf. He was happy to say, however, that they were waking up. This was no new problem. He had recently come across a little book published in 1648, in which the subject of lip reading was discussed. Thirty-five or forty years ago Dr. Wilhelm Meyer, of Copenhagen, read a monograph before the Royal Chirurgical Society on adenoid vegetations, which was thorough and complete, even from the critical viewpoint of to-day, on that important subject. He was hissed out, and it was two years before the ideas he promulgated regarding adenoid vegetations took root in the mind of medical men, and ten years after that before the first operation for the removal of adenoids was performed in this country. So it required time to digest a new idea before it would be put into application. Last year he had talked to the Jackson County Medical Society in Kansas City and the teachers of the deaf and social workers had the children of the Oral School for the Deaf in Kansas City give a demonstration. It was the first time the specialists had heard these children trained in their own home town. They confessed that they had not visited the school, but pledged themselves to look into the matter. He saw the head teacher six months later, who told him none had appeared. The deaf child was a peculiar psychological and pedagogical entity, and could not be treated exactly like the normal child. His lack of methods of communication until he could read left him somewhat slow in comparison to normal children, and until he acquired that form of instruction his little brain was in a condition of excommunication from the world about him. Neurologists had diagnosed such children as morons but when put in possession of a means of communication some of these children soon outdistanced the normal children about them. The education of the congenitally deaf child should begin at the age of three and a half years instead of at six years, and it would be found that he progressed as rapidly at this age as the normal child of six or seven years. Those who had made a study of pedagogical methods were firmly convinced that there was but one form of training for the congenitally deaf child, and that was oral training. Signs and the manual alphabet belonged to past and antiquated educational methods. By oral methods were meant speech and lip reading. Children could be taught speech reading as easily and rapidly as they could be taught signs or manual methods, and when they had received the oral training they had the advantage of not being ostracized from those about them. It was easier to teach lip reading to the congenitally deaf child than to the adult who had acquired normal speech. Dr. Goldstein outlined the measures that were being taken to initiate a great national movement for the better training of the deaf. He stated that Dr. Richardson, Dr. Kenyon, and himself, together with others interested in this work, had held a conference and formulated plans which would be submitted at the coming meeting of the American Medical Association for the approval of that organization. This committee was called the Committee on the Education of Deaf Children, and it proposed to make every effort to stimulate the entire medical profession to a realization of the importance of this question. The plan also provided for children with speech defects. They had held conferences with representatives of the Carnegie and Rockefeller Foundations, and were receiving their cooperation. Efforts would be made to standardize schools for the deaf, as had been done in the case of medical schools. From the standard of greatest efficiency, though he supposed he would be considered rather harsh to say it, he believed the teacher of lip reading should not be so deaf that she or he was not able to hear the individual pupil. The teacher who was unable to hear could not correct voice, pitch, accent, or pronunciation, and was not doing justice to the cause of lip reading to the child, or to the public. He preferred the term speech reading to lip reading, because it included the expression of the face, gesture, the shrug of the shoulder, all of which were as important as the movement of the lips. He felt that this was a very momentous movement and that every medical man should be cognizant of it, that the medical profession should give it their valiant support, not an indifferent cooperation, but they should come forward with actual practical suggestions and real support.

Demonstration of Reconstruction Section of Defects of Hearing and Speech.—Dr. CHARLES W. RICHARDSON of Washington gave this presentation by invitation. He stated that the Section of Defects in Hearing and Speech in the Division of Reconstruction of the Surgeon General's office was given definite form on March 1, 1918. Shortly thereafter he was assigned as director of the section. Before entering upon his duties he had made a careful study of the problems connected with this activity, and after the usual "ups and downs" incident to establishing a new procedure, they found that on July 23, 1918, they were actually a working section with a full active unit. During the period of organization they had so perfected their plans that at the end of the service, December 15, 1919, they found it totally unnecessary to alter them in any way. One of their greatest difficulties in preparation was to obtain statistics as to the probable number of patients requiring this form of treatment. The most reliable that they were able to obtain came from Major Dundas Grant of London, who held a somewhat similar position in the British Army as the writer did in the American Army. They had finally calculated one-half of one per cent. to the total number of wounded, and this they found was greater than the actual results. They had enrolled upon their list one hundred teachers in speech reading who were anxious to enter the service as reconstruction aides under full army regulations. Their list of instructors in speech defects was not quite so large. They were forced to call on only a few of these for speech reading and speech defects. It was due to the superintendent, principal, and instructors to state that he never expected to find a better equipped, more intelligent, more enthusiastic, and more devoted band to labor in any field of human endeavor than this body. They had one object in view, that was the making of a perfect speech reader out of every patient that was presented, and they came very near to the full accomplishment of the task. Individual temperament and mental status of the patient was the only obstacle that prevented them from the full accomplishment of the result. The methods employed in their work were those known as the Muller-Walle method. Miss Bruhn's text book on the Muller-Walle method was selected as a basis for the work. They had also made use of the Nitchie method. They were as catholic in their efforts as possible to obtain good results. They followed out the usual routine method in all cases, although there was a considerable amount of speech reading taught "by doing it." They resorted to the use of mirrors, blackboard illustrations, demonstrations, and the use of the Northampton charts. It had also been their in-

tention to make use of moving picture demonstrations, but they had found that unnecessary. The method of teaching was an intensive one. Each patient was at first given one or two lessons a day, which were rapidly increased to two or three periods a day, care being taken that no patient suffered mental fatigue from overwork. The time employed at each period was forty-five minutes. In the section of defects in hearing, 112 patients were treated and in the section of defects in speech, 54 patients. The reports of the Home Service Section of the American Red Cross, who followed up these patients, agreed generally with the standard of the patient when he was discharged, and indicated not only that they had gained results, but that the good results were maintained by the men many months after they were discharged from the service. He hoped to be pardoned for saying that their results were unexpectedly great. He believed the work accomplished by this section marked an advance in the teaching of speech reading to the deaf. It also demonstrated that a high grade of intelligence was not necessary to acquire facility in speech reading. They had had all types of minds, all grades of education, and all forms of temperaments, but not one required, nor was it necessary to give to any one the manual method of training. These efforts had brought more forcibly to the American medical mind the fact that the deaf could be placed upon a purely independent plane through speech reading than through any other method of which he was aware. It was possible that the method of intensive training instituted in their work might be of some service in the instruction of the lay deaf.

How the Deafened Rebuild Their Lives.—Miss ANNETTA W. PECK, executive secretary of the New York League for the Hard of Hearing, told how this organization was helping people to conquer the limitations of a handicap whose cruelty was refined to a high degree. She said that the victims of acquired deafness constituted a very considerable number of each community, and of these the ones who surrendered body and soul to the enemy were in an overwhelming majority. Yet practically every one of them might be reached and inspired to turn on that enemy and conquer gloriously. The impulse to rise and win, it must be admitted, almost invariably was applied from without, and it was in the administration of this external force that the deafened found their own greatest spiritual opportunity. Proceeding on the general principle that no one could understand a condition like him who lived under it, the deafened social worker sought to attract the despondent and all but demoralized victim of adventitious deafness by appealing to certain universal needs—the need of economic independence, the need of easier communication, the need of wholesome play, and the need to be of service. In his blighted state the deafened person out of a job read an inconspicuous "ad." in the want column of his newspaper: "Jobs for the hard of hearing. Apply at the free employment bureau of the New York League for the Hard of Hearing." Another might read that the city was conducting a free class in lip reading at the league's rooms; still another might chance upon a letter to the editor, telling about one of the league's recreation clubs and the good times enjoyed in it. At all events, hope was born, and that hope would draw until some time it might not be for months, courage was plucked up to call at the league's office. In every instance, except those few who expected deafness to be miraculously healed or exorcised, the man or woman got what he or she came for and got it abundantly. It was not too much to say that he got more; for from that moment when he opened his heart and his life to receive what he sorely needed, his reconstruction began. He was in contact with the external force, and under its pressure he turned at once to rebuilding his life. He became a self-supporting, contented, hopeful, happy man; unconsciously he then proceeded to build another story to his tower—the pinnacle of service. In reclamation work among the deaf the deafened man of riches might well join his weapons to those of the social worker. These two must be the faithful co-adjutors of the doctor's experience, while the doctor should join heartily with them in the active cooperation which alone could make their dreams come true. By means of aural examination of school children, of school clinics for the prompt treatment of conditions which arose most often during the school years; by teaching hard of hearing children the art of lip reading and giving them small recitation groups in the regular subjects without segregating them from hearing children; by the elimination of hereditary disease and infectious diseases; by making researches where these activities demanded, by all these means the end might be attained. The machinery for carrying on the work was already organized, incorporated, and ready to function in the form of the American Association for the Hard of Hearing. In closing, Miss Peck made a plea for the social worker, the physician, and the man of wealth to give this national movement their moral and financial support.

The Psychology of the Deafened from a Layman's Standpoint.—Mr. JOHN DE RAISMES STOREY (a Harvard graduate, lawyer, counsel for the Red Cross Commission in Italy, completely deaf) said that for many years he had been striving to make himself believe that the psychology of deafened people was like that of other people. Ideally it would be true that the deafened had mental processes and traits similar to those of any haphazardly selected large group. Practically, however, the limitations of the deafened and the overemphasis in their lives of certain problems tended to develop certain qualities and certain faults, and there was such a thing as a typical deaf man. To his mind the besetting sin of his afflicted brethren was fear and its derivatives, timidity, self-consciousness, sensitiveness, etc. They were afraid of being conspicuous, of being laughed at, and the covert smile they detected on the faces of many presumably decent folk when they had to be shouted at cut like a lash. Americans, as a rule, did not covet being different from their neighbors in superficial things; they liked to do the things others were doing, but to do them better, and to be like others but superior. It was just here that the deaf person was at a disadvantage. He might be a man of natural parts and cultivated attainments, but in social intercourse he felt his inferiority to the most callow youth. The deafened man knew that in social intercourse the account opened with a debit against him, as the one talking to him must shout or put himself out in some other way; and it was then hard for the deafened man to be self-forgetful. Unless the latter was a person of unusual social gifts and aptitudes he was prone to avoid as much as possible general companionship with others and gradually to withdraw within himself, not because of any genuine disposition to live alone, but because it was the line of least resistance. In this social isolation were developed practically all the mental and moral consequences which characterized the typical deafened man or woman—shyness, self-consciousness, self-centeredness, sensitiveness, queerness, discouragement, depression, timidity, the sense of shame at being hard of hearing, and all the other faults which human beings developed when they were much more by themselves than they were intended to be. Obviously this mental make-up impaired one's chances in the business world. Some fields of undertaking were necessarily closed. In others it was hard for the deafened to get an opportunity and he might be obliged to take some uncongenial inferior task because employers were too indifferent, timid, or uninspired to offer him a chance. Thus there was danger of his standard of living being lowered and his chance of social intercourse minimized, and all the faults developed by his deafness would increase. The great task of the deafened was therefore to overcome his fears. He must refuse to be a typically deafened man, and endeavor to be successfully deaf, that is, he must strive to live a normal, wholesome life, with an occupation suited to his capacities, with friends, hobbies, wide interests, etc., and not let his affliction affect his character except beneficially. To a large extent the physical aspects of his problem could be overcome, and in ways that went far to remove the psychological difficulties. Lip reading and the electrical devices invented of recent years were by no means perfect substitutes for hearing, but in many cases they offered a real opportunity to live a normal, wholesome life. Mr. Storey related his personal experience in overcoming his han-

dicap. The psychology of the deafened person, however, was not the only one to be considered. He would have to blame the public for making his task more difficult. The public had its typical psychological reaction to the deafened man. Pity, not unmingled with impatience, and then indifference, was the lot of most deafened people. They were avoided. They were not given a chance to take their place in the social and economic world. They had not been told that a deafened man could be companionable, useful, sympathetic, amusing, perhaps, in short, all that a friend should be. In the business world there was much that a deafened man could do. He was not easily distracted; he had not the same temptation to loiter in conversation as the normal of hearing, he could concentrate more readily. Personally he did not feel that the deafened man should accept a humble task if he was fitted by attainments for a better one, though there might seem to be difficulties in his way. In his experience it had been the big men that gave the deafened the opportunity to show his worth. The small man saw only the difficulties; the big man appraised the difficulties, but looked at the balance well. Nearly all the speaker's professional opportunities had been given him by people of exceptional ability. It was this fact which led him to feel confident that the deafened, in cooperation with the enlightened among the public, led by the doctors, would be able to reclaim to useful citizenship many who would otherwise become among the flotsam and jetsam of life.

Ears and the Job.—Miss ESTELLE SAMUELSON, superintendent of the Employment Bureau of the New York League for the Hard of Hearing, told how they had solicited the cooperation of business firms in getting employment for the hard of hearing. Interviews frequently laid bare the employer's ignorance of the hard of hearing, and how little thought they had given to the subject of deafness. To such persons they related what other employers reported about their hard of hearing employees. A hard of hearing person was an asset in a business office because he concentrated better than others. A hard of hearing person was more efficient at general routine work because he was accustomed to monotony and isolation. A hard of hearing person did more work in less time because he did not engage in the constant chatter going on around him. A hard of hearing person was reliable and appreciative of his employer's effort to train him because he recognized his limitations and did not seek constant change. A hard of hearing person was a master of detail.

In placing the deafened individual they always made a complete survey to ascertain the nerve strain and tension, amount of standing, dampness, varying temperature, and amount of exposure, if any. It was always their desire to place applicants where the conditions of work were such as to conserve whatever hearing he had. They now had the cooperation of 379 firms, and were making new connections daily. In the study of the types of work that were suitable or injurious for a man with this handicap they needed the aid of the otologist. They were trying to obtain scientifically accurate reports as to the type and degree of deafness. Being acquainted with their aim, the doctor who quite frequently knew the individual better than they or more intimately, offered a most valuable suggestion toward vocational selection. Their records showed that only 75 per cent. of the applicants registered in the past year had had aural examination or treatment; 39 per cent. were slightly hard of hearing, 44 per cent. hard of hearing, and 17 per cent. totally deaf. During the year 1919 they had had 272 applicants and had found positions for 207. They had helped to increase the efficiency and value of a number of them by proving to them the advantage of making their powers of comprehension greater, so that association with them would be more agreeable and less trying to the people who employed them. They were urged to attain a mastery of lip reading or to use a hearing device, if possible.

Dr. EDWARD B. DENCH said he hoped the audience had all learned as much as he had this evening. It did not take so much energy to be a surgeon where one could see the results of his work in a brilliant light, but it took courage to do a work such as had been seen here this evening, and he paid tribute to those engaged in it. They saved the mind and soul of these deafened people so that, as had been pointed out, they could commingle with their fellow men and occupy positions of responsibility and contribute their quota of service, and perhaps a larger one than many who could hear well did. Dr. Goldstein brought out an important point when he said that the training of the deaf child should begin early. He believed that was the best advice. He had seen one example of that in a boy who had learned to speak both French and German, and was prepared for college. Such examples as this showed what education would do. With reference to adult deafness, that was a most important question and concerned otologists even more than the problem of the deaf child, though that was highly important. The otologist saw cases becoming progressively hard of hearing, and he should advise such persons to take up lip reading. Then if they lost their hearing they would be lip readers, and if their hearing was only partially impaired the lip reading would assist them in hearing.

Miss CARRIE KEARNS, principal of the New York Public School for the Deaf, told of her experience in this school where she had the supervision of 300 congenitally deaf children. She said she agreed with all the previous speakers had said. The important factor in this work was to follow up all along the line. When you gave a new language exercise you followed it up until the child acquired it; the child was followed up all through school, and when it came to the last year was given assistance in selecting and preparing for an occupation. After the young people went out and took positions the school still continued to keep in touch with them and guide them.

Dr. EDWIN L. LACROSS, principal of the Wright Oral School, said that like Dr. Goldstein, he wanted to interest medical men in this question. Miss Peck had given them her cooperation, but they needed the cooperation of medical men. The physician was the person not only to tell the parents of the deafness of a child, but to point out the unlimited possibilities that lay before the deaf child, and it was the duty of the parent to assist the deaf child to take advantages of the opportunities offered him. He quite agreed with Dr. Goldstein that the training of the deaf child should be begun early, between the third and fourth year. Effort should be made to develop any residual hearing that the child might have. Fifty per cent. of the pupils at the school with which the speaker was connected were given auricular training and for the most part with benefit.

Mr. FREDERICK MARTIN, director of speech Improvement of the Board of Education, said his work with 900,000 children led him to speak of deaf children. Two points he wished especially to bring out: one was to emphasize the importance of auricular training; the other was about the sign language. He knew from his work in connection with speech defects that the sign language was still being taught. He thought this was something this body of physicians should take up, as it was a mistake to permit it to be continued. In spite of the wonderful work of the teachers of lip reading, he thought they should work through the auricular paths in cases in which there was any hearing left. He cited instances in which children supposed to be deaf were not really unable to hear, but simply lacked the perception of sound. Such children could be trained to recognize sound.

Miss JOSEPHINE TIMBERLAKE, associate editor of *Volta Review*, said she did not know whether she had understood correctly that Dr. Goldstein said that a teacher with perfect hearing could produce better results as a teacher of lip reading than one who was too deaf to hear the sound of the human voice. She said she did not know many teachers of lip reading who had perfect hearing, but she did know of many who were deaf and were producing excellent results. She felt that it was very disheartening to the deafened who hoped to serve others by teaching lip reading to feel that they were not so well suited for the work as those who had perfect hearing.

Dr. GOLDSTEIN, in closing, made a plea for an effort to develop a system of lip reading which should embrace the best points of the various systems now in use.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

CONNECTICUT STATE MEDICAL EXAMINING BOARD.

November, 1919.

ANATOMY.

1. Name the bones of the foot and describe the astragalus.
2. (*a*) Give the location of, and (*b*) describe the pituitary body.
3. Describe the blood.
4. Describe the mesentery, giving especial attention to distribution of blood vessels.
5. Describe an internal iliac vein.
6. Name tendons of thigh muscles that cross knee joint which have to do with flexion of leg on thigh, giving insertion of each.
7. What muscles cause displacement of extremities of fragments in fracture of clavicle at middle third of bone?
8. Describe the articulations between movable vertebræ. Diagram if preferred.
9. What are the three primary kinds of joints?
10. Describe briefly the development of bone.

PHYSIOLOGY.

1. What is the composition of normal urine?
2. What is the rôle of the large intestine in the digestion and absorption of food?
3. What are enzymes? Name a few. How do they aid in the process of digestion?
4. What factors influence the movements of the stomach?
5. To what extent may intra-thoracic pressure be influenced by respiration?
6. Name the events that occur during a single cardiac cycle.
7. Comment upon the various functions of leucocytes.
8. What is the function of, and mechanism of action of the iris.
9. What difference is there in the paralysis from injury to the spinal and the pyramidal neuron?
10. What chemical changes take place in muscle during contraction?

ANSWERS.

ANATOMY.

1. *Bones of the foot.* Seven tarsal (os calcis, astragalus, cuboid, scaphoid, and internal, middle and external cuneiform); five metatarsals; and fourteen phalanges.

The astragalus is situated between the tibia above and the os calcis below, and receives directly the weight of the body. It has the scaphoid bone in front, and on each side it is in contact with the malleolus (that of the fibula, on the outer side; and that of the tibia on the inner side). The bone is usually described as having a head, neck, and body. It gives attachment to the external and internal lateral ligaments of the ankle joint. On its under surface there is a deep groove for the interosseous ligament, and on the posterior surface is a groove for the flexor longus hallucis.

2. (*a*) The *pituitary body* is a ductless gland, situated on the sella turcica of the sphenoid bone, under cover of the diaphragma sellæ; in the center of this latter structure there is an opening for the passage of the infundibulum.

(*b*) It consists of two lobes, the anterior of which is the larger and belongs to the digestive tract; the posterior lobe, which belongs to the nervous system, is connected with the tuber cinereum of the brain by means of the infundibulum.

3. The *blood* is fluid, somewhat viscid, red, specific gravity from 1,055 to 1,062, alkaline reaction, saltish taste, characteristic odor, variable temperature (average about 100° F.). The *constituents* are plasma and corpuscles. The *plasma* consists of water and solids (proteids, extractives, and inorganic salts). The *red corpuscles* consist of water and solids (hemoglobin, proteins, fat, and inorganic salts). The *white corpuscles* consist of water and solids (protein, leuconuclein, lecithin, histon, etc.). The *red cells* are biconcave discs, about 1/3200 of an inch in diameter; they are nonnucleated, and there are about 4,500,000 or 5,000,000 of them in each cubic millimeter of blood. They are elastic and soft, and their shape is changed by pressure, but is promptly regained on the removal of the pressure. Their color is yellowish. They contain hemoglobin. They carry oxygen from the lungs to the tissues. The white blood cells are spheroidal masses, varying in size, having no cell wall, and containing one or more nuclei; there are about 7,000 to 10,000 of them in each cubic millimeter of blood. They differ much in appearance, and are divided into (1) small mononuclear leucocytes, or lymphocytes; (2) large mononuclear; (3) transitional; (4) polynuclear, or polymorphonuclear, or neutrophile, and (5) eosinophile. They are all more or less granular, particularly the last two varieties named. They are probably formed in the spleen, lymphatic glands, and lymphoid tissues. Their fate is uncertain: it has been asserted that they are converted into red blood cells; they play a part in the formation of fibrin ferment; they are sometimes converted into pus cells. Their functions are (1) to serve as a protection to the body from the incursions of pathogenic microorganisms; (2) they take some part in the process of the coagulation of the blood; (3) they aid in the absorption of fats and peptones from the intestine, and (5) they help to maintain the proper proteid content of the blood plasma.

There are also *platelets*, which are very small, colorless, irregular shaped bodies; they are about one-fourth the diameter of a red corpuscle. The function is not determined; it is possible that they take some part in the coagulation of the blood. In number they vary from about 200,000 to more than 500,000 in each cubic millimeter of blood.

Plasma serves to convey nutriment to the tissues; it holds in solution the carbon dioxide and water which it receives from the tissues, and takes them to be eliminated by the lung, kidneys, and skin; it also holds in solution urea and other nitrogenous substances that are taken to and excreted by the liver or kidneys. *Arterial blood* is bright red in color, contains more oxygen, less carbon dioxide, more water, and is slightly warmer; *venous blood* is purple in color, contains less oxygen, more carbon dioxide, less water, and is slightly cooler (except in the hepatic vein). It is distributed through the body by the heart, arteries, capillaries, and veins.

4. *The Mesentery.* "The root of the mesentery begins on the anterior surface of the fourth part of the duodenum in front of the left side of the second lumbar vertebra, and extends downwards and to the right. It crosses, successively, in front of the third part of the duodenum, the aorta, the inferior vena cava, the right ureter and the psoas major, and terminates in the right iliac fossa at the ileo-cecal junction. This line of attachment is only six or seven inches in length, and, in order to enclose the twenty-three feet of intestine, the mesentery spreads out in a fan-shaped manner and becomes very much pleated near the gut. Its depth varies, being as much as seven or eight inches at its deepest part. The two peritoneal layers of which it consists contain between them nerves, blood-vessels, lymph vessels (lacteals) and glands, and a varying amount of fat. The latter is more thickly deposited along the root, and it diminishes in quantity as the mesentery is traced to the intestine. . . . The intestinal arteries form a series of twelve to fifteen branches, which arise from the left side of the superior mesenteric artery and pass towards the jejunum and ileum. They break up into branches which unite and reunite to form a connected series of arcades, which are more complex in the ileum than in the jejunum. From the terminal arcades, small branches pass to the mesenteric border of the gut and there bifurcate."—(Beesly and Johnston's *Manual of Surgical Anatomy.*)

5. *The internal iliac vein* is a short vein, extending from the upper border of the great sacro-sciatic foramen to the sacro-iliac articulation at the brim of the pelvis, where it unites with the external iliac vein to form the common iliac vein. It is formed by the union of the superior vesical, middle vesical, inferior vesical, middle hemorrhoidal, uterine and vaginal (in the female), obturator, internal pudic, sciatic, lateral sacral

and gluteal veins. It lies behind and internal to the internal iliac artery, and is in relation internally with the pelvic colon on the left side, and with the lower part of the ileum on the right side. The internal iliac vein has no valves.

6. *Tendons of thigh muscles which cross the knee joint and have to do with flexion of the leg.*—(1) *Sartorius*, inserted into the inner surface of the upper part of the tibia, near the tubercle. (2) *Biceps*, inserted into the head of the fibula and outer tuberosity of the tibia. (3) *Semimembranosus*, inserted into the back of the inner tuberosity of the tibia, and into the posterior ligament of the knee joint. (4) *Semitendinosus*, inserted into the upper part of the inner surface of the tibia. (5) *Popliteus*, inserted into the triangular surface above the oblique line of the tibia.

7. *In fracture of the clavicle at the middle third*, the *outer fragment* is drawn (1) *downward* by the weight of the limb, and the action of the pectoralis major, pectoralis minor, and latissimus dorsi; (2) *forward* by the pectoralis major, pectoralis minor and serratus magnus; (3) *inward* by the pectoralis major, pectoralis minor, levator anguli scapulæ, and latissimus dorsi. The *inner fragment* may be drawn a little *upward* by the sternomastoid.

8. The *articulations of the vertebral column* consist of joints between the bodies of the vertebræ and joints between the neural arches by means of the articular processes. The former are amphiarthroses, the latter diarthroses. The *bodies* are united by the anterior common ligament, the posterior common ligament, and the intervertebral substance. The laminæ are connected by the ligamenta subflava. The articular processes are surrounded by the capsular ligaments. The ligaments of the spinous processes are: The interspinous ligaments, the supraspinous ligament, and the ligamentum nuchæ. The intertransverse ligaments extend between the transverse processes.

9. The *three forms of articulations* are: (1) *Synarthrosis*, or immovable articulation, such as that between the two parietal bones. (2) *Amphiarthrosis*, or mixed articulation, such as that between the two pubic bones. (3) *Diarthrosis*, or freely movable articulation, such as that between the humerus and the ulna.

10. *Development of Bone.* "The development of bone is either intramembranous or endochondral. In the latter a cartilage stage intervenes, otherwise the history in each case is the same. A synopsis of endochondral development is as follows: (1) A solid shaft of hyaline cartilage, non-vascular and without any marrow cavity. (2) In the center of this shaft the cartilage cells enlarge, their lacunæ enlarge and coalesce, particularly along lines extending toward the ends of the bone. The rosette produced by this excavation is called the primary areola of Sharpey. (3) Lime salts are deposited in the thin walls of these spaces, making calcified cartilage. (4) Osteogenetic cells and blood vessels from the periosteum enter the cartilage spaces. The cartilage cells disappear with this invasion and the excavation, begun by the cartilage cells, is further enlarged by the bone cells. The excavated areas are now called the secondary areolæ of Sharpey, the cavities having a rich blood supply quite in contrast with the primary areolæ. The marrow cavity is excavated and the shaft becomes longitudinally porous. Endochondral bone, therefore, develops *in* cartilage, not *from* cartilage. (5) Osteogenetic cells attach themselves to the wall of these enlarged Haversian canals and become enclosed in lime deposits, forming thus the outer lamellæ and outer row of bone cells of each Haversian system. Cells with lamellæ are added centripetally to this outer row and thus ultimately complete the Haversian system, leaving a small central canal containing vessels and a nerve. Ossification begins in the center of the cartilage shaft and proceeds gradually toward each end, so that all the above changes occur at one and the same time. After birth these changes go on at the ends of the bone, so long as it keeps growing. During this period the bone is made thicker by deposits from the periosteum forming the circumferential lamellæ of bony shafts. These lamellæ are added without the intervention of a cartilage stage and therefore represent intramembranous development."—(Hill's *Histology.*)

PHYSIOLOGY.

1. *Composition of urine:*

	(Parts in 1000)	
Water	950.00	Organic
Urea	28.00	
Uric acid	0.60	
Hippuric acid	0.35	
Creatinin	0.65	
Extractives	8.00	
Sodium chloride	8.00	Inorganic
Phosphoric acid	2.00	
Sulphuric acid	1.25	
Lime (CaO)	0.25	
Magnesia (MgO)	0.30	
Potash (K_2O) and soda (Na_2O)	0.60	
Total	1000.00	

2. *Digestion and absorption in the large intestine.* "The secretion of the large intestine, while it contains much mucus and shows an alkaline reaction, is not characterized by the presence of distinctive enzymes. When the contents of the small intestine pass the valve they still contain a certain amount of unabsorbed food material. These contents remain a long time in the large intestine, and since they contain the digestive enzymes received in the duodenum the digestive and absorptive processes no doubt continue as in the small intestine. This general fact is well illustrated in experiments made upon dogs, most of whose small intestine (70 to 83 per cent.) had been removed. These animals could digest and absorb well, and formed normal feces, provided care was taken with the diet. An excess of fat or indigestible material caused diarrhea and serious loss of food material in the feces. An interesting feature in the large intestine is the marked absorption of water. In the small intestine water is absorbed no doubt in large quantities, but its loss is evidently made good by osmosis or secretion of water into the intestine, since the contents at the ileocecal valve are quite as fluid as at the pylorus. In the large intestine the absorption of water is not compensated by a secretion; the material loses water rapidly while in the ascending colon, and before it reaches the descending colon it has acquired the consistency of the feces. The alkaline reaction of the contents of the large intestine makes a favorable environment for the growth of bacteria, particularly the putrefactive bacteria that attack protein material."—(Howell's *Text-Book of Physiology.*)

3. *Enzymes* are substances produced by living cells and which act by catalysis. The enzyme remains unchanged and exerts its activity only upon certain definite substances.

ENZYMES.	ORIGIN.	FUNCTIONS.
Ptyalin.	Saliva.	Changes starches into dextrin and sugar.
Pepsin.	Gastric juice.	Changes proteids into proteoses and peptones in an acid medium.
A curdling ferment.	Gastric juice.	Curdles the casein of milk.
Trypsin.	Pancreatic juice.	Changes proteids into proteoses and peptones, and afterward decomposes them into polypeptides and amino-acids in an alkaline medium.
Amylopsin.	Pancreatic juice.	Converts starches into maltose.
Steapsin.	Pancreatic juice.	Emulsifies and saponifies fats.
A curdling ferment.	Pancreatic juice.	Curdles the casein of milk.
Invertin.	Succus entericus.	Converts maltose into glucose.

4. *Movements of the stomach.* "When devoid of food the stomach remains in a condition of slight tonic contraction, the mucous membrane being thrown into folds. *X*-ray observations have shown that in the empty condition only the pear-shaped upper third of the stomach contains gas, the rest of the organ passing to the pylorus in the form of a collapsed tube, which corresponds in position to the small curvature of the filled stomach. Food when swallowed causes relaxation of the walls of the stomach. Moreover, the food introduced at different times bears different relations with regard to the stomach walls. That is to say, food first introduced is spread round the stomach, forming a lining to the mucous membrane. Food introduced later is retained encapsuled like a ball by its enveloping layer of mucin. This fact is of extreme importance, for the later food is protected from the gastric juice, and the admixed saliva, which is inactive in an acid medium, is enabled to prolong its activity. Cannon maintains that salivary digestion may proceed even for an hour or more after the food is in the stomach. Soon after the introduction of food into the stomach, movements begin. These proceed at first very gently, but later on increase in intensity. They are confined entirely to the pyloric portion of the stomach. Cannon, by his recent feeding experiments with bismuth subnitrate and *x*-ray observations, has succeeded in observing the movements of the stomach very closely. They consist of a series of contractions, which proceed in a peristaltic manner. The sphincter at the commencement of the pyloric vestibule contracts, in a ring-like manner, and this contraction is propagated over the pyloric portion. The time taken in transit is twenty-six seconds (in the cat), and the successive contractions follow one another at ten-second intervals. By this means the food in the pyloric region of the stomach is thoroughly disintegrated and mixed with the gastric juice. When this condition is reached the pylorus is relaxed at certain intervals and portions of the acid chyme are ejected into the duodenum. Immediately succeeding this the pylorus again enters into tonic activity. The relaxations of the pylorus coincide with the arrival at that place of a wave of contraction, although they are irregular; for every peristaltic wave there is a corresponding pyloric inhibition. It is in the pyloric vestibule of the stomach that the food is so thoroughly mixed with the gastric juice, and it is here also that solid food is most likely to injure the mucous membrane of the stomach, and so predispose to the formation of gastric ulcer. So far no mention has been made of the functions and movements of the fundus and body of the stomach. These portions do not undergo contractions in rhythmic series, but the musculature enters into a condition of maintained strong tonicity. The function of this is obvious, and is to replenish the pyloric triturating apparatus with further materials from the fundus and body store."—(Lyle's *Psysiology.*)

5. *Influence of respiration on intrathoracic pressure.* "For the pressure conditions existing within the lungs and pleural cavity, slightly different figures are given by different investigators. Due to the fact that the lungs are in a state of permanent distension within an air-tight cavity, the intrathoracic pressure is always negative under normal conditions, this negative pressure being, of course, greater during inspiration, less during expiration, and also being somewhat affected by posture. Under forced expiration, however, where the air passages are obstructed, the intrathoracic pressure may become positive, as for instance during a violent coughing attack where there is obstruction to the expiratory blast. The intra-pulmonary pressure, on the other hand, varies with the phase of the respiration, being negative during inspiration, positive during expiration."—(Osler and McCrae's *Modern Medicine.*)

6. *Cardiac cycle.* "We may begin with the closure of the semilunar valves. At that moment the second heart sound is heard and at that moment the ventricle is quickly relaxing from its previous contraction. Since the auriculoventricular valves are still closed, the ventricles for a brief interval are shut off on both sides. The blood is flowing steadily into the auricles and dilating them. As soon as the ventricles relax, the pressure of blood in the auricles opens the auriculoventricular valves, and from that moment until the beginning of the auricular systole the blood from the large veins is filling both ventricles and auricles. The venous blood which has been accumulating in the auricles during the ventricular systole flows into the ventricles with some suddenness on the opening of the auriculoventricular valves. The ventricles, therefore, dilate rapidly and the auriculoventricular valves are floated into a position ready for closure. . . . The auricular systole sends a sudden wave of blood into the ventricles, dilating them still further and momentarily blocking or retarding the flow from the large veins. The ventricular systole follows at once upon the auricular systole. As the ventricle enters into contraction the auriculoventricular valves are tightly closed, the first sound is heard, and for a short interval the ventricular cavity is again shut off on both sides. Soon the rising pressure in the interior forces open the semilunar valves, and then a column of blood is discharged into the aorta and pulmonary artery as long as the contraction lasts. During this interval the flow at the venus end of the heart continues, the blood being received into the yielding auricles. . . . At the end of the ventricular systole the excess of pressure in the aorta and the pulmonary artery closes the semilunar valves and completes the cycle."—(Howell's *Physiology.*)

7. *The functions of the leucocytes* are: 1. To serve as a protection to the body from the incursions of pathogenic microorganisms; (2) they take some part in the process of the coagulation of the blood; (3) they aid in the absorption of fats and peptones from the intestine, and (4) they help to maintain the proper proteid content of the blood plasma.

8. *Function of and mechanism of action of iris.* "For purposes of distinct vision it is essental that the quantity of light entering the interior of the eye shall be so adjusted that the formation and subsequent perception of the image shall be sharp and distinct. This is accomplished by the iris, the circular fibers of which alternately contract and relax with increasing and decreasing intensities of the light. The size of the pupil, therefore, through which the light passes, will vary from moment to moment and in accordance with variation in the light intensity. The quantity of light necessary to distinct vision is thus regulated. In the total absence of light the sphincter pupillæ muscle is relaxed and the pupil widely dilated. With the appearance of light and an increase in its intensity the muscle again contracts and the pupil progressively narrows. With a given intensity in the light, the sphincter contraction is greater when the light falls directly into the fovea. Contraction of this muscle also occurs as an associated movement in the convergence of the eyes during accommodation and in consensus with the other eye. In addition to this function of the iris, it constitutes, by virtue of the sphincter muscle contraction, an important corrective apparatus. Being non-transparent, it serves as a diaphragm intercepting those rays which would otherwise pass through the peripheral portions of the lens and by spheric aberration give rise to indistinctness of the image. The movements of the iris by which the size of the pupil is determined are caused by the contractions and relaxations of the *sphincter pupillæ* and *dilator pupillæ* muscles. The contraction of the sphincter is entirely reflex and involves those structures necessary to the performance of any reflex act, viz.: a receptive surface, the retina; afferent nerves, the pupillary fibers of the optic nerve; a central emissive center situated in the gray matter beneath the aqueduct of Sylvius; and efferent nerves, the motor oculi and the ciliary nerves. The stimulus requisite to the excitation of this mechanism is the impact of light waves or ether vibrations on the rods and cones. According to the intensity of these vibrations will be the resulting contraction of the muscle. The contraction of the dilator pupillæ muscle is determined by the activity of a continuously active nerve-center in the medulla oblongata which transmits its nerve impulses through the spinal cord, along the first and second dorsal nerves to the superior cervical ganglion, and thence to the iris by way of the fifth nerve. These two muscles appear to bear an antagonistic relation to each other, for section of the motor oculi is followed by relaxation of the sphincter muscle and dilatation of the pupil. Stimulation of the sympathetic is followed by a more pronounced dilatation. The size of the pupil

is the resultant of a balancing of these two forces." —Brubaker's *Text-Book of Physiology.*)

9. *Differences in paralysis of upper motor neuron and lower motor neuron:*

UPPER NEURON.	LOWER NEURON.
1. Diffused muscle groups affected, never individual muscles.	1. Individual muscles may be affected.
2. Spasticity and hypospasticity of paralyzed muscles.	2. Flaccidity and atonicity of paralyzed muscles.
3. May have superadded associated movements on attempted voluntary movement.	3. No associated movements.
4. No muscular atrophy, except from disuse.	4. Atrophy of paralyzed muscles.
5. Electrical reactions normal.	5. Reaction of degeneration.
6. Deep reflexes in paralyzed limbs present and usually increased.	6. Deep reflexes of paralyzed muscles diminished or absent.
7. If foot affected, plantar reflex, extensor in type.	7. Plantar reflex, if present, is normal flexor type (unless flexors of toes are themselves paralyzed).

—(Hunt's *Diagnostic Symptoms in Nervous Diseases.*)

10. The *chemical changes which occur in a muscle during contraction* are: (1) It consumes more oxygen; (2) it sets free carbon dioxide; (3) it produces sarcolactic acid; (4) it becomes acid in reaction; (5) it produces heat; (6) it loses glycogen.

Death of Glénard.—Glénard of enteroptosis fame died recently in his home at Vichy. In an obituary notice in the *Gazette des hôpitaux* for May 29, xcii, 49, an incomplete biographical sketch is given. He fought through the Franco-Prussian war as a soldier and was a prisoner at Stettin, the home of Brand of typhoid fever fame. Through this accident Glénard was later led to introduce the Brand method of treatment into France. He was as prisoner an orderly under Brand and at the time took many notes. After the completion of the war he finished his medical studies at Lyons. For a long time he strove to introduce the Brand method into the Lyons and Paris hospitals and ultimately the movement was successful. This service has been forgotten in the work of the author on enteroptosis which made him one of the best known physicians in the world and shed lustre on French clinical medicine. This work was synchronous with the first growth of the specialty of gastroenterology and did its bit in the extinction forever of the notion of "dyspepsia" as an autonomous disease. At a date not stated the author went to Vichy to take charge of the thermal hospital at that town, and it was the unsurpassed material of gastric, hepatic, nervous, and other subjects which came constantly to Vichy that made possible his book on enteroptosis, which is one of the great medical classics. So thoroughly did he perform his work that it was accepted at once. A son, Roger Glénard, resides at Vichy and continues his father's life work.

The Medical School of French West Africa.—This institution is discussed by Le Dantec in *Le Bulletin Médical* for May 29, 1920, xxxiv, 28. The idea which has given birth to this institution is recognition by the French Government of the great part played by the West African colonials in the defense of the mother country during the great war. The author is director of the new school which began its teaching in November, 1918. The name is somewhat misleading, for the seat of the institution is in Paris, and not, as the title seems to imply, in some African city like Dakar. The men to be trained for practice as colonials receive their training in the European metropolis, so that the school corresponds to institutions like the Liverpool School for Tropical Medicine. There are four departments—medicine, pharmacy, midwifery, and veterinary medicine. Colonial men and women, presumably largely African, will be trained in these branches, special courses being given to the native women in the calling of midwife. The course of medicine is four years, the first year comprising preliminary training in physics, chemistry, etc. Clinical instruction will be provided for, and among the teachers will be practitioners from the Dakar hospitals. In the pathology taught special stress will be laid on the diseases peculiar to the black races. For teaching midwifery a special maternity hospital will be created. The graduate midwife will be more than her name signifies, as she will be responsible for minor gynecology and pediatrics. The courses in midwifery and pharmacy are three years each.

THE INTERPRETATION AND CLINICAL SIGNIFICANCE OF UTERINE HEMORRHAGE.*

BY EMIL NOVAK, M.D., F.A.C.S.,

BALTIMORE, MD.

(From the Gynecological Department of Johns Hopkins Medical School.)

THE fact that normal menstruation is in itself a form of uterine hemorrhage—the only physiological hemorrhage occurring in the human body—makes the study of this function the natural point of departure in the study of abnormal uterine bleeding. It is probably not an overstatement to say that more has been learned concerning the mechanism of menstruation during the past two decades than during many centuries preceding. The study of the steps by which modern scientific methods have gradually pushed aside the old cobwebs of mysticism and speculation concerning the study of menstruation, constitutes one of the most interesting chapters in the history of gynecology. Time will permit, however, of only the most summary statement of our modern conception of the physiology of menstruation.

Factors in Normal Menstruation.—The underlying cause of menstruation is universally conceded to be the internal secretion of the ovary. While there has been considerable discussion as to which constituent of the ovary is responsible for this menstrual hormone, the evidence points rather overwhelmingly to the corpus luteum as the responsible factor. This structure, beginning its life history immediately after the rupture of the mature Graafian follicle, passes through a series of developmental stages, which call forth a similar cyclic response in the endometrium. The latter tissue reaches the acme of its hypertrophic development, the stage of premenstrual hypertrophy, just before the onset of menstruation.

The cardinal feature of the menstrual phenomenon has usually been assumed to be the marked pelvic hyperemia which occurs. A moment's thought, however, must convince one that hyperemia of the endometrial vessels cannot in itself explain such an extensive migration of blood elements into the cavity of the uterus as is found during menstruation. So that it is necessary to presuppose the presence in the endometrium at this period of some local physiological factor which increases the permeability of the blood-vessel walls and allows of a massive exodus of blood elements, especially red blood corpuscles. Finally, the nerve mechanism of the pelvis, especially that of the vasomotor nerves, plays a part in the menstrual process; while even the influence of the higher centers cannot be overlooked. These matters I have discussed in previous papers, but their application may again be emphasized as concerns the mechanism of uterine bleeding.

Types of Uterine Hemorrhage.—In perhaps the majority of cases of uterine hemorrhage, it is possible to demonstrate a definite anatomical basis for the bleeding. This is preeminently the case with such destructive lesions as cancer, or with those endometrial conditions associated with the retention of embryonic products. In cases of this type the bleeding is clearly due to the opening up of blood-vessels by the disease process. Bleeding occurs in uterine cancer for the same reason that it occurs in cancer of the rectum, stomach, or other organs. Menstruation plays no essential part in hemorrhage of this type, although it may exaggerate the severity of the symptom.

In a second class of cases, both anatomical and physiological factors seem to be operative. Perhaps the best illustration of uterine bleeding of this variety is furnished in the ordinary cases of chronic inflammatory disease. The usual explanation given for the bleeding which is so often found in this condition has been that it induces a marked pelvic hyperemia, which thus exaggerates the bleeding associated with menstruation. There are several objections to this theory. In the first place, hyperemia, in itself, cannot, as has already been emphasized, explain the extensive diapedesis of blood elements seen in the ordinary cases of menorrhagia. Again, even in the case of the most severe grade of pelvic inflammation, the endometrium is often perfectly normal; while, on the other hand, menstruation may be normal, or even absent, in cases of acute endometritis, which is certainly characterized by more intense hyperemia than is seen in cases of chronic adnexitis. For such reasons as these, Hitschmann and Adler have championed the theory that the uterine bleeding seen with most pelvic abnormalities, such as myoma, adnexitis, uterine displacements, etc., is due to functional involvement of the ovary. It seems to me that there can be no doubt that such functional disturbances of the ovary are at least in part responsible for uterine hemorrhage in this type of case. On the other hand, it seems equally certain that other factors play some part in the causation of this form of uterine bleeding.

Finally, uterine hemorrhage may occur in the entire absence of any gross disease in the pelvic organs. In cases of this type we must seek the

*Address delivered at the annual meeting of the West Virginia State Medical Association, Parkersburg, W. Va., May 20, 1920.

explanation chiefly along the lines of perverted physiology, as will be discussed later.

There is scarcely a lesion of the female generative organs which may not be associated with uterine bleeding in the form of either menorrhagia or metrorrhagia or both. It is scarcely necessary to enumerate these causes categorically. For the purposes of this brief paper it has seemed to me wiser to select for this discussion only a few of the most important causes of uterine hemorrhage, illustrating, as they do, the principles which have already been set forth.

Cancer.—The first place in such a presentation should perhaps be given to cancer of the uterus, in view of its frequency and its extreme gravity to the patient. In over 90 per cent. of all cases of this disease, the first symptom noted by the patient is uterine bleeding, which, therefore, constitutes a far more valuable warning than pain. The latter is rarely observed until the disease is well advanced. Bleeding usually occurs at an earlier period in the external types of uterine cancer, especially squamous cell carcinoma of the cervix, than in the intrauterine varieties, which are better protected from such traumatic influences as friction against the vaginal wall, etc.

So much has been preached as to the early recognition of cancer that one hesitates to harp again upon the same string. And yet every gynecological surgeon knows, and every general practitioner of medicine should know that in spite of these oft-repeated warnings, the majority of cases of uterine cancer which come to the gynecological surgeon have already passed the stage where surgery can promise a fair measure of hope. I cannot, therefore, resist the temptation to lay this matter before you again. Who is responsible—the patient, the family physician, or the surgeon?

The responsibility of the patient in cases of uterine cancer rightfully pertains to that period elapsing between her own recognition of abnormal symptoms and the day on which she consults her physician. Unfortunately, there is an even earlier stage, dating from the earliest inception of the growth to the appearance of the earliest symptom, and for this period no individual can be held responsible. This preliminary period is of varying length, but in some cases, as in adenocarcinoma of the cervix, the patient's doom may be sealed before a single symptom is noticed. Unfortunately, however, women are prone to delay, even after abnormal symptoms, usually uterine bleeding, make them apprehensive. The causes for this delay are chiefly the following: (1) The belief that abnormal bleeding at this age is merely an evidence of "change of life." (2) The idea that no such serious condition as uterine cancer can be present when the patient experiences no pain and is in good general health. (3) The dread which many patients have that, if a gynecological operation be submitted to, cancer may be found. (4) The erroneous idea held by many individuals that cancer is always an incurable disease.

It is in this first stage of the disease that the patient herself plays the chief rôle, and it is with the shortening of this stage that we are concerned in any popular campaign of cancer education. It cannot be too strongly urged that such a campaign of education should carry with it a note of encouragement. Women should know the possibly grave significance of uterine bleeding, but they should also be impressed with the frequent curability of uterine cancer in its earliest stage, and by the fact that hemorrhage is by no means always indicative of cancer. Only in this way can we dispel that dread of cancer which is often the chief reason for the patient's delay in seeking advice.

The second stage comprises the period between the patient's first consultation with her physician and the time at which she is referred to the gynecologist. It is unfortunate but true that even at this day this period is frequently much too long. The delay, in the case of the physician, is rarely due to ignorance; much more frequently to carelessness or to a species of "professional inertia." There is still room for education within our own ranks.

The third stage dates from the time at which the patient comes under the care of the gynecological surgeon. The latter, with all his other sins, may fairly boast that he is rarely culpable in delaying treatment in cases of uterine cancer which are brought to his notice. His own principal responsibility lies in the judicious selection of cases for radical operation, and in the perfection of his own technique, so as to lower the high immediate mortality in operations for the radical removal of uterine cancer.

Benign Lesions of the Cervix.—Among other anatomic causes of uterine hemorrhage may be mentioned such relatively simple conditions as erosion of the cervix, or the more common eversion, or ectropion, so frequently associated with cervical laceration. In the latter condition, the everted cervical mucosa is often engorged to such an extent that it bleeds on the slightest touch or after the slightest trauma. In these cases metrorrhagia, usually slight, is observed after coitus, or after severe exertion. The same mechanism is involved in the not infrequent cases of cervical polypi, especially if they protrude beyond the cervical canal. In the case of polypi springing from points higher up in the uterine canal, bleeding more frequently takes the form of menorrhagia, for obvious reasons.

Retained Gestation Products.—Perhaps the most frequent cause of uterine bleeding of the anatomical type, or of any type, for that matter, is the retention of gestation products after abortion. The large blood vessels in the placenta and in the uterine wall are often the source of the most profuse hemorrhage, caused directly by the efforts of the uterus to expel the foreign material. It is surprising how much tissue may in some cases be retained in the uterine cavity without causing any serious bleeding, while, in other cases, even a very small amount may be productive of alarming hemorrhage. Once the placental tissue has been thrown off from the uterine wall into the uterine cavity, it is, as a rule, no longer a source of great danger from the standpoint of hemorrhage, except as it prevents the uterus from contracting. If it remains attached, however, bleeding is apt to be kept up from blood vessels ruptured by the contractions of the uterus, in an effort to expel the retained tissue. This does not always follow directly

after the delivery or the miscarriage. Recently a woman was admitted to my service almost exsanguinated from bleeding occurring suddenly seven weeks after an apparently normal delivery. Evacuation of the uterus yielded a typical placental polyp, the result of the retention of a placental cotyledon.

Other Pelvic Lesions.—In the case of pelvic inflammatory disease, the explanation which has usually been given for the bleeding is that this condition causes a pelvic hyperemia which is responsible for the abnormal bleeding. There is much evidence, however, to indicate that a more important factor is to be found in the associated functional disorder of the ovary. This evidence I have reviewed in previous papers, and I shall not elaborate on this point here.

It must not be assumed, from what has been said as to the importance of the ovarian rôle in the causation of the bleeding in this group of cases, that other factors play no part whatsoever. In the case of uterine myoma, for example, there can be no doubt that the mechanical factor due to the presence, the size, and the location of the tumor is of the greatest importance. It is a well-known fact that bleeding from myomatous tumors is, speaking generally, more profuse in the submucous type than in the intramural or subperitoneal variety. The splendid researches of Sampson throw an interesting light on this question.

Another lesion which may be classed under this general group is ectopic pregnancy. The uterine bleeding so characteristic of this condition is no doubt chiefly due to a perverted physiology, but its mechanism is interesting and rather unique. While there is some difference of opinion on this point, it seems to me that the evidence is quite convincing that the hemorrhage—meaning, of course, the external or vaginal bleeding—is directly due to the death of the embryo. A number of interesting cases have come under my observation which throw some light on this question. I shall mention the three which I think are most striking:

Several years ago I operated on a woman of 35, who had been referred to me by Dr. B. S. Rankin, of Tunnelton, W. Va. She had missed two menstrual periods and had exhibited the usual subjective signs of pregnancy. Several days before I saw her she had been taken with violent pains in the left iliac fossa, and had suffered a number of syncopal attacks. There had, however, been no external hemorrhage whatsoever. Examination showed a slightly enlarged uterus, and a large, sensitive mass filled the left side of the pelvis. In spite of the absence of uterine bleeding, a diagnosis was made of ruptured tubal pregnancy. At operation the pelvis and lower abdomen were found to be filled with blood, the left tube being the seat of a ruptured pregnancy. This was confirmed by microscopic examination of the tube. The patient made an uneventful recovery. About six weeks after the patient's discharge I was rather chagrined to receive a letter from Dr. Rankin stating that the patient had had an attack of uterine bleeding, with some pain, followed shortly afterward by the expulsion from the vagina of a three-months' fetus. The explanation of the case was then quite clear. The woman, at the time of operation, had had a combined intra- and extrauterine pregnancy, the uterus being pregnant at the time of the removal of the tube. There was no way for us to determine the existence of the uterine pregnancy at the time of operation. The presence of the live fetus within the uterus explained why she had no external hemorrhage.

The second patient was a woman of 39, who came to me on January 24, 1920, through the kindness of Dr. B. F. Kader, of Baltimore. She had been married many years and had had one child 21 years previously. There had been no pregnancies since then. Menstruation had been regular until November 29, which was the date of the last regular period. Since then there had been complete amenorrhea. Three weeks before admission the patient was taken with severe pain in the lower abdomen, especially marked in the left iliac fossa. These pains had been present since that time and had often been very violent. On the day of admission the patient was suffering excruciating pain, with nausea and some vomiting. At operation there was found a very much enlarged pregnant tube, from the fimbriated end of which there protruded an intact amniotic sac about the size of an orange. To the latter was attached the placenta, which was also beginning to emerge from the tube. Within the sac was a fetus of about three months' development, apparently living. The specimen, after removal, was examined by Dr. Streeter, of the Carnegie Institute of Embryology, who stated in his report that the fetus was undoubtedly alive at the time of operation. This would seem to explain the entire absence of uterine bleeding in this patient.

The third case was a rather remarkable instance of abdominal pregnancy, which I operated upon only a few weeks ago. The patient was a woman of 36, who was referred to me by Dr. B. O. McCleary, of Baltimore. The patient had been married fourteen years without previous pregnancy. The date of the last regular menstrual period was March 21, 1919. About March 31 the patient was taken with severe pain in the epigastrium, with vomiting, and was uncomfortable for several weeks. Following the menstrual period in March, there was complete amenorrhea, and the patient considered herself pregnant. The abdomen gradually increased in size, and fetal movements were perceived in September. On December 20, at about the time the patient expected to be delivered, she was surprised at the occurrence of a rather profuse menstrual flow, lasting about ten days. In January, 1920, there was amenorrhea, but the menses occurred regularly on February 19 and March 18. When I saw her on April 12, 1920, the abdomen was enlarged to the size of a full-term pregnancy, although the fetal parts could not be clearly outlined. The breasts showed a slight hypertrophy and a moderate amount of milk (not colostrum). Vaginal examination showed the cervix to be small and not very edematous, while extending upward toward the left iliac fossa, and apparently continuous with the cervix, was an indefinite, firm body, giving the impression of a non-pregnant uterus. Without going into further detail, I may say that a diagnosis was made of abdominal pregnancy, with retention of a dead fetus. This was borne out by the operation, the details of which I shall not stop to describe. My reason for mentioning this case is the fact that it illustrates some of the factors which are concerned with the uterine bleeding in cases of ectopic pregnancy. Throughout the course of the entire pregnancy this patient showed no metrorrhagia, but as soon as the death of the fetus occurred in December there was a profuse discharge of blood, menstruation thereafter occurring regularly, with the exception of the month of January. The amenorrhea in this month, it seems to me, is explainable by the onset of lactation, the hormone of the lactating breast, as is well known, exerting an inhibitory effect on menstruation.

Functional Uterine Hemorrhage.—Perhaps the most interesting type of hemorrhage is the kind which is observed not infrequently in the entire absence of any demonstrable pelvic disease. This type of bleeding has been spoken of variously as "functional," "idiopathic" or "essential" uterine hemorrhage. It is of very frequent occurrence, especially at the two extremes of menstrual life, puberty and the menopause. It may, however, occur at any age. In these cases the most careful examination may show perfectly normal pelvic organs, and yet bleeding may be persistent and perhaps very profuse. Most commonly it takes the place of menorrhagia rather than metrorrhagia.

Cases of this type usually come to curettage sooner or later, and indeed, in the case of climacteric hemorrhage, the indication for this procedure is urgent, owing to the importance of excluding carcinoma. In the non-malignant climacteric cases and in those of puberty, the pathological report on the curettings has usually been some such designation as "normal endometrium," "hypertrophic glandular endometritis," "chronic endometritis," etc. It has seemed difficult to incriminate the endometrium as the cause of bleeding of this type. Equally unsatisfactory have been the efforts to explain this form of bleeding by such factors as arteriosclerosis of the uterus, the insufficienta uteri of Theilhaber, etc.

The point which I should like to emphasize is that the endometrium in a very large proportion of these cases—I am not prepared as yet to put it in percentage figures—conforms to the type described by Cullen as *hyperplasia of the endometrium*. The histological picture presented by this condition is extremely characteristic. As the term indicates, there is a general hyperplasia of the uterine mucosa, with an increase of both the epithelial and stromal elements. Owing to the epithelial proliferation, many of the glands become much enlarged and of cystic appearance. The disparity in the glands is, perhaps, the most conspicuous feature of this condition on casual examination, so that as a rule the diagnosis may be made almost at a glance. That the cystic condition of the glands is not due to mere retention of the contents is suggested by the fact that the epithelium, instead of being flattened out, is commonly quite intact. Not infrequently the epithelial cells are seen to be several layers thick. The stroma is also markedly increased and occasionally mitoses are noted. Grossly, the endometrium in these cases is almost always much thickened, sometimes enormously so. In the extreme cases curettage will often bring away large masses of fungoid tissue, which look for all the world like a malignant condition. In other cases the thickening is relatively slight.

An endometrium of the type above described is never observed except in association with the symptom of uterine bleeding. The reverse is, of course, not true, for uterine hemorrhage may be due to many anatomic causes. It is of interest, however, to note that with certain pelvic lesions, especially myoma and adenomyoma, the endometrium may exhibit the condition of hyperplasia, as above described. There is some evidence to believe that both myoma and adenomyoma are due to some as yet unknown aberration of ovarian function, and, as we shall see, there is little doubt that the same factor is responsible for hyperplasia of the endometrium.

The finding in a case of uterine bleeding of such a definite structural alteration as hyperplasia of the endometrium would seem at once to take such a case out of the category of functional hemorrhage. There is strong evidence, however, that this characteristic change in the endometrium does not represent a primary lesion, but that it is purely secondary to a disturbed function of the ovary. Under normal conditions the endometrium is certainly subordinate to the influence of the ovary. The ever changing histological appearance of the uterine mucosa at different phases of the menstrual cycle is undoubtedly called forth by corresponding cyclical changes in the ovary, and especially in the corpus luteum. So that there is nothing revolutionary in the idea that the characteristic picture of hyperplasia may be associated with some definite endocrine disturbance of the ovary.

Hyperplasia, generally speaking, is observed only during the reproductive life of the woman, that is, during the period of ovarian activity. This fact in itself would suggest some influence on the part of the ovary. Furthermore, curettage, in cases of hyperplasia, is most frequently unsuccessful in the relief of the accompanying hemorrhage, the latter symptom recurring in a large proportion of cases. Were the hyperplasia a local lesion in the endometrium, its removal should be followed by cure. That this is not the case would seem to indicate that the underlying cause, an endocrine disorder of some sort, still remains operative. Although repeated curettage frequently does not cure these cases, radium of the *x*-ray usually brings about the cessation of the abnormal menstruation, apparently by its destructive action on the follicles of the ovary. As a matter of fact, there is strong evidence, as has already been stated, that almost all cases of uterine hemorrhage, with the exception of those due to such destructive lesions as cancer, are functional in the sense that the bleeding is, in part at least, due to disturbances of the ovarian secretion, as the result of the pelvic disease, whether this be myoma, or pyosalpinx, or what not.

Conclusions.—The points in the above presentation which seem worthy of special emphasis are the following:

1. The logical basis for the study of uterine hemorrhage is the study of normal menstruation.

2. In many cases uterine bleeding is explainable along purely anatomic lines, especially in the case of such destructive lesions as cancer.

3. In perhaps the largest group of cases—those in which there exist one or more of such non-destructive lesions as adnexitis, myoma, uterine displacement, etc., both mechanical and functional factors play a rôle, the latter having to do most frequently with a disordered ovarian function. In the case of ectopic pregnancy, still another factor must be borne in mind—that exerted by the death of the embryo.

4. The third group, comprising the cases of uterine hemorrhage spoken of clinically as functional, is dependent altogether upon a disordered ovarian function. The hyperplasia of the endometrium so frequently found in these cases is secondary to this underlying ovarian endocrinopathy.

26 East Preston Street.

Sarcomatous Transformation of Uterine Fibroids.—Paulhiac, in a recent Bordeaux thesis, states as a result of revised statistics that at least 5 per cent. of uterine fibroids will meet with this fate, the danger being greatest towards the menopause years. The transformation is usually suggested by increased rapidity of growth, but this may escape observation. Hysterectomy, unfortunately, often proves to have been only a palliative recourse. The danger from sarcomatous alteration, in these cases, the author says, is an added reason for the routine ablation of certain fibroid uteri.—*Gazette hebdômadaire des sciences médicales de Bordeaux.*

PARENTERAL PROTEIN TREATMENT OF ARTHRITIS, WITH SPECIAL REFERENCE TO MILK INJECTIONS; ITS RELATION TO ANAPHYLAXIS.

By M. SCHULMAN, M.D.,

NEW YORK.

ASSOCIATE IN MEDICINE, COLUMBIA UNIVERSITY.

THIS communication is prompted by several facts. At a recent symposium on the treatment of arthritis, held before a medical society that generally, as on this occasion, calls forth a large attendance of general practitioners, an orthopedic specialist who was scheduled to read a paper on vaccine treatment of arthritis, laughed the subject off and sat down. In the few moments that he spoke and during which he, in sarcastic tones condemned the method, he included, as even more foolish than specific vaccine therapy of arthritis, non-specific protein treatment of the same conditions. His reasons were that we don't understand the rationale, and that an assistant of his reported unfavorable experience with the methods. I hope to show that the reasoning here illustrated is not sufficiently sound to warrant the neglect of a possibly very useful therapeutic procedure.

Then, while there have appeared a number of good articles reporting on the parenteral protein treatment of arthritis, I came across none by English or American authors, speaking of the use of milk as the foreign protein. This in spite of the fact that Schmidt used milk by intramuscular injection, already in 1910,[1] and during 1916 there appeared in German and Austrian literature a number of articles on the use of milk for parenteral injection in the treatment of various affections, including arthritis. Reports that struck me as particularly interesting in this connection were those of Muller and Thanner,[2] of Friedlander,[3] and of Dziembowski.[4]

I began the use of milk injections early in 1917. My experience with parenteral protein treatment is almost exclusively with milk as the protein and with infectious arthritis as the disease, and is limited to about five dozen cases. I shall not give case histories nor statistics, but, after an attempt at elucidation of what is known of, and what has been accomplished with, the method, will briefly outline my experiences and technique.

When foreign protein treatment is mentioned, it is fair to say that, in the minds of a great many, an association with anaphylaxis is immediately awakened. The cerebration formula seems to be: Protein, foreign, anaphylaxis. To the medical mind it seems clear that for anaphylaxis protein is necessary. The most generally accepted view to-day does hold that this reaction is limited to protein antigens. And it is well to hold this clearly and firmly in mind. When Richet in 1902[5] coined the term, he used it as the antithesis to prophylaxis. The Standard Dictionary defines "anaphylaxis" only under "prophylaxis," and then makes the important omission of failing to mention protein. I speak of all this because if we do want to understand what parenteral protein treatment does, and if we are to differentiate it from anaphylaxis, it is necessary to understand the basic principles of anaphylaxis as far as they are to-day understood. It therefore seems in order to note briefly some of these fundamental facts.

Magendie in 1839 reported meeting with sudden death in some experimental dogs whom he had repeatedly injected with egg albumin. Flexner in 1894[6] noted active sensitization of rabbits to dog serum, but it was not until Richet[5] took up the study of anaphylaxis in 1902 that it became a purposeful one and stimulated study of the phenomenon by many workers.

In 1905[7] the very important fact was noted that, while an injection of horse serum given to a guinea pig (and let it be noted that most experiments in anaphylaxis are carried out in guinea pigs, because these animals are very susceptible to protein sensitization, while some other animals are highly resistant) sensitized the animal to another dose given after an interval of 10 to 12 days, the repeated injection of the animal with considerable quantities, at *short* intervals, rendered the animal refractory or immune to later injections. This latter condition is that of "anti-anaphylaxis."

Some of the most important and detailed work on this subject was done by Milton J. Rosenau and Anderson, working in the U. S. Public Health Service.[8] These workers established the following facts:

1. A single injection of horse serum into a guinea pig is harmless.

2. A second injection after a definite interval is harmful.

3. This interval or incubation time, with ordinary doses, is about ten days.

4. The anaphylactic reaction which results from a second injection is highly specific. There are few undoubted instances of non-specific anaphylaxis; the specificity is as a rule one of species. It is very interesting to note "organ specificity." Thus, the protein of the crystalline lens is specific. It will sensitize toward lens protein from any and all species of animals, but the lens protein of an animal will not sensitize toward any other protein of that animal. It may be noted that an explanation along these lines has been offered for sympathetic ophthalmia.

5. The reaction is extremely delicate. Only proteins act as anaphylactic antigens. Lipoids are by some said to act as such antigens, but this is doubtful. The chemical nature of the anaphylactic poison is not clearly understood.

6. The hypersusceptible state is not transient. It may last a long time; Rosenau and Anderson found it to persist in a guinea pig as long as 1,096 days, and they express the belief that it may last a life time. Please note this fact carefully.

7. Antitoxins, precipitins and hemolysins have nothing to do with the reaction.

8. The sensitive condition is transmissible to offspring; a very important fact.

There may be passive sensitization as well as active. Passive sensitization may persist 3 to 4 weeks. It may be accomplished in several ways, as follows: (1) by the injection of serum from a sensitized animal; (2) by the injection of serum from an animal in the preanaphylactic period, as on the eighth day after it was injected; (3) by

the injection of serum from an anti-anaphylactic animal; that is, an animal that has been rendered refractory, as by the repeated injection at frequent intervals.

Note further, the young of anti-anaphylactic animals are not refractory, but are hypersusceptible.

In passively transferring anaphylaxis, an interval of some hours (4 to 24) is required before the newly injected animal becomes sensitive. This point must be carefully noted, for it is a strong argument for the "cellular" theory of anaphylaxis. It thus seems that the sensitizing agent must become attached to or react with the fixed cells of the passively sensitized animal, before this animal becomes sensitive.

"We may accept as a definitely determined fact that anaphylaxis is directly or indirectly the result of the reaction within the animal body, of an antigen with its specific antibody. In *active* anaphylaxis the antibodies are present as the reaction to a preceding antigen injection. In the *passive* condition, they were conveyed with the injected antiserum. A hypersusceptible subject, temporarily desensitized by antigen, will again gradually become sensitive."[9]

Anaphylaxis is a general systemic reaction; its local analogue is called allergie.[10]

Anti-anaphylaxis, or desensitization, is best produced by giving a second dose of the antigen in the latter part of the incubation period (or preanaphylactic period). Small doses of antigen produce the susceptible state earlier than do large doses. Repeated doses given at frequent intervals may act merely as one large dose, prolonging the incubation period but leaving the subject finally sensitive. Please note this last fact carefully for its bearing on foreign protein treatment.

Pfeiffer,[11] in 1909, noted depression of temperature during anaphylaxis and this is considered an essential phenomenon of the reaction. Note the contrast between this and infection, where elevation of temperature is characteristic. At about the same time it was found that complement is reduced during the development of shock which follows the second or toxigenic dose of protein.[12] During the shock there is also lowered blood coagulability and temporary leucopenia. Eosinophilia is characteristic in anaphylactic reactions.

Acute anaphylactic shock results in respiratory death. The resemblance to an attack of violent bronchial asthma was noted by Meltzer, and his pupils, Auer and Lewis,[13] studied the condition on animals kept alive by artificial respiration. They found the bronchioles in tetanic spasm, imprisoning air, and resulting in large, non-collapsible, emphysematous lungs. They further proved the mechanism to be peripheral, and not central, for they could produce the condition with vagi cut, or cord and medulla destroyed. Furthermore, they could resolve the bronchial spasm by atropine, which pharmacologists know exerts its effect peripherally on the nerve terminals. This was a most important piece of work with an immediate, practical applicability.

In 1906 VonPirquet and Shick[10] described serum sickness. This is believed to be a manifestation of anaphylaxis, though it needs some explaining in view of the fact that the train of disturbances designated as serum sickness will appear after the *first* injection of serum, but after an incubation period of one to twelve days. The cases of serum sickness which appear only after a second injection, are, of course, easier to understand. These usually appear after briefer incubation periods, and are apt to be more severe. They may even be "immediate" and "accelerated" reactions. The severity of a serum reaction is in proportion to the size of the dose. In case of serum disease following a second injection, the severity is in proportion to the length of the interval elapsing between the first and the second injections. The best explanations offered for the appearance of serum sickness following a first injection are: (*a*) that the patient had been previously accidentally or unconsciously sensitized to the now injected serum; or (*b*) during the incubation period which follows the first injection of serum, the antigen (injected serum) is gradually split by native antibody, until finally a sufficient quantity of excess antibody has been stimulated into being to unite with the remaining antigen (and fix alexin) and produce the anaphylotoxin, with the consequent symptoms. Thus the antigen destroyed early in the incubation period sensitizes the patient to the remaining quantity.

Vaughan's[14, 15, 16] work with protein split products is a most important American contribution, and has a possible very close bearing on our subject. He split the protein molecule into alcohol soluble and alcohol insoluble fractions. The alcohol soluble fraction is toxic, but non-sensitizing; the alcohol insoluble fraction is non-toxic, but is sensitizing. Following the first injection of protein, according to this conception, the substance is slowly broken up, with the liberation of the two fractions. The alcohol insoluble, sensitizing fraction acts as an antigen, calling forth the production in excess of antibody (lysin, enzyme). When, later, protein is again injected, it meets this excess of antibody with the consequent rapid lysis of the reinjected protein, the explosive liberation of the toxic fraction (anaphylotoxin), and anaphylactic shock results.

A group of protective bodies necessary to consider in this connection are enzymes, which are present in probably every fluid and every cell of the body, and which are highly important in the completion of metabolism and final assimilation of proteins, carbohydrates, and fats. The parenteral introduction of almost any substance, and especially bacterial protein, produces a marked increment of the enzymes of the blood, including proteolytic, amylolytic, and lipolytic. The ferments so appearing are *non-specific*. The increased serum activity after protein injection may be due to the simultaneous increase of ferment production and diminution of antiferments. The mechanism is probably a mobilization of ferments normally present but not concentrated in the blood stream under ordinary conditions. This is suggested by the fact that the appearance of these substances is accomplished with a speed out of all harmony with the rate of production of other antibodies. The enzymes also disappear very rapidly after the stimulus is removed.

Now as for sneering at non-specific therapy be-

cause there is no adequate understanding of the mechanism, let us appraise somewhat what has been accomplished to demonstrate its value from the laboratory standpoint and by clinical experience.

The father of *specific* vaccine therapy, Sir A. E. Wright,[17] in 1915 admitted that good results by non-specific methods, formerly considered unscientific, are nevertheless frequently encountered.

Theobald Smith said in 1910,[18] "The effectiveness of vaccine applied in the course of acute febrile diseases, such as typhoid and pneumonia, must be accounted for by principles of which experimental medicine has as yet no definite knowledge." That is an admission of inability to explain a fact, but not therefore denial of the fact.

It was Fraenkel in 1893[19] who noted that he could benefit typhoid patients by subcutaneous injections of typhoid vaccine. This was obviously contrary to expectation based on the theory of specific vaccine stimulation. Here, too, because fact ran contrary to theory, it was long neglected.

Rumpf[20] very soon did something even much more shocking to orthodoxy, for he accomplished with subcutaneous injection of *pyocyaneous vaccine* what his friend, Fraenkel, had done with his typhoid vaccine. Then Matthes[21] showed that he could produce a tuberculin reaction with *deutero-albumose*, and that the tuberculin fraction contains toxic protein in addition (foreshadowing Vaughan's work). But it was Ichikawa's[22] introduction of *intravenous* injection of typhoid vaccine in typhoid patients that was most striking in its results and that led to the further use of protein intravenously for non-specific purposes, for Kraus[23] very soon observed that colon vaccine intravenously gave the same results in typhoid as did typhoid vaccine; Lüdke[24] obtained good results in typhoid with deutero-albumose (non-bacterial protein split product); F. P. Gay[25] in this country reported good results from the intravenous injection of sensitized typhoid vaccine in typhoid cases; while Jobling and Peterson[26] studied the subject very carefully in animals, and reported good results in typhoid patients by the intravenous use of typhoid vaccine. Jobling and Peterson in a second article[27] say in discussion of the results encountered, "The fact should be kept in mind that the effect is not specific, and that there have been found no immediate changes in the antibody concentration of the patient after the injection of the vaccine. There remains the possibility that the non-specific ferments of the body are stimulated and in some way bring about the destruction of the invading organisms and a detoxication. An increase in the protease might produce a more rapid splitting of the toxic protein fragments to lower, non-toxic forms, while an increase in the lipolytic ferments may have some influence in destroying the infecting organism itself. At the time of the crisis in pneumonia a definite increase in serum protease is demonstrable. In experimental animals we have found that the intravenous injection of killed bacteria is followed by a mobilization of non-specific ferments." These same investigators continued their study of the mechanism of "The Non-Specific Factors in the Treatment of Disease," and their work is so careful and relevant that I am tempted to quote them again. In 1916 they say, "Latterly the hemopoietic organs have come to be recognized as the chief source of antibodies. It would seem possible that the various agents act as stimulants of the hemopoietic tissue, which as a consequence suddenly floods the body with antibodies, thereby overcoming the infection. If this is the mechanism involved, it is important to keep in mind that the stimulus itself is not a specific factor, but that the hemopoietic system has been attuned to respond to a non-specific stimulus with the production of specific substances. Serumprotease, as other tryptic ferments, is without effect on bacteria; but if we consider the source of the intoxication occurring in the diseased organism as primarily due to protein split products, then such a mobilization of protease may be of considerable importance in the process of detoxication, in that the toxic fragments are hydrolyzed to lower and non-toxic forms."

Finally, Jobling opens his Harvey Lecture of February, 1917,[28] as follows: "The therapeutic measures used in the treatment of infections may be divided into two general classes: First, those specific substances which are supposed to destroy the infecting organism or neutralize its toxins, and, second, those which aim to strengthen the natural processes that normally bring about recovery." He concludes this lecture thus: "That the intravenous injection of non-specific substances exerts a marked influence on those infections in which it has been tried is very evident. It is not believed, of course, that these newer methods will cure all cases of infection. They do, however, open up new possibilities and suggest new methods for attacking infections of unknown etiology, and also those caused by organisms for which we have no specific antiserums. That all cases are not benefited does not necessarily reflect on the value of the treatment. There are very few therapeutic measures which do not have the same objection."

The clinical experiences heretofore quoted have dealt almost entirely with typhoid fever, but they led up to the use of these substances in other conditions, notably arthritis, and it is to this subject that we shall now turn. The first application of the method to cases of arthritis, in this country, was reported by Miller and Lusk[29] of Chicago, in June, 1916. They used typhoid vaccine and proteose intravenously, in cases of acute, subacute, and chronic arthritis with striking benefit, and with apparently equal results with the vaccine and the proteose, so that they later discarded proteose, finding the vaccine more convenient. In December of the same year[30] they reported further experiences with a large series of cases and find themselves encouraged to continue the method. Following this lead, we have reports on the use of the method, with good results, from a number of men. Cecil[31] used typhoid and also gonococcus vaccine intravenously. He got better results in cases of rheumatism than in cases of gonorrheal arthritis. Snyder[32] had a series of 110 cases of all types of arthritis, some in very bad condition and of long standing. He used typhoid vaccine intravenously and reports very good results. Boyd[33] used intravenous vaccine in cases of arthritis, myositis, etc., with reported good results. Duncan and Fraser[34] used "detoxicated" vaccine intravenously, with good results, and seem to feel that the "detoxication" by long storage of the vaccine makes their intravenous

use safer than fresh vaccine. Gow[25] used intravenous peptone plus sensitized vaccine and reports good results in various conditions, but especially in arthritis. He makes the notable statement that best results were obtained in multiple infective arthritis where no primary focus was demonstrable.

From what has already been said it will appear that there seems considerable warrant in reports of clinical experience for the therapeutic use of parenteral protein, and that, although the method had its origin before there was satisfactory explanation of its mechanism, yet approach to an understanding has been accomplished. It will further appear that the method has met with considerable success in various forms of arthritis, but that practically all the work reported outside of German literature has been with intravenous injection of bacterial vaccine. As already indicated, my own experience with the method has been almost entirely with milk as the antigen. I have used it in about five dozen cases of arthritis, with gratifying results in the great majority, and with results that make one enthusiastic in *gonorrheal* arthritis.

The method consists in injecting *intramuscularly* (not intravenously) with all the precautions as to asepsis and avoidance of entry into a vein that are commonly employed in giving insoluble mercury, for example, of cow's milk that has been sterilized by boiling for about five minutes, and subsequently cooled to a comfortable temperature. The initial dose for an average sized adult is 4 c.c. The injection is generally repeated every other day, and the dose is increased by 1 c.c. at every injection. The total number of injections required varies with the individual case, and may be anywhere from two to ten. I have never given more than ten injections to a case, for I always had reason to think at the end of such period that we had obtained all the good possible; the patient was either well, or had ceased to show progressive improvement. The increase in dosage also is not a fixed and constant matter, but will depend on the degree of improvement and more especially on the severity of constitutional reaction that the patient showed. When the patient has a severe reaction the dose injected following such reaction should not be increased at all over the previous one; it rarely has to be reduced. To get any good out of the treatment a constitutional reaction must be produced. If none results after two or three injections, the method must be changed. Intravenous protein injection may then produce a reaction and a cure, where the intramuscular had failed. For intravenous use some bacterial protein seems best, especially since this has been most used and something is known of the proper dosage. If it is not convenient to carry out the treatment at home, it may generally be quite safely given at the office or clinic. The patient should then be directed to go immediately home, go to bed, and stay in bed the rest of the day. The reaction following an intramuscular milk injection rarely comes on in less than one and a half hours, and this gives the patient, in most instances, ample time to get home before its onset. The symptoms (to be outlined further on) rarely last more than eight hours; but in the exceptional cases, where they last longer, the patient should be directed to remain in bed as long as there is any fever or other constitutional discomfort. Local disturbance at the site of injection is never severe enough to incapacitate the patient. I have seen several patients who showed, after the second or later injection, a local allergic reaction, but this was never severe enough to cause much inconvenience. The time interval between injections should be as stated, unless there is some good reason for lengthening it, as when the reaction is unduly prologed. An injection should not be repeated before the symptoms from the preceding one have entirely disappeared. It is hardly necessary to mention, after what has been said when discussing anaphylaxis, that the second injection should never be given, unless it can be given after an interval of less than ten days. In view of the opinion expressed by Rosenau and Anderson (mentioned above) that an animal may possibly be rendered sensitive to foreign protein for a lifetime, it would be much safer, in the event that a course of parenteral protein treatment had been interrupted for some time and it was desired to resume such treatment, to resume it with a protein from a different species.

Provided the intramuscular injection of milk gives as good therapeutic results as do the intravenous injections of various proteins suitable for intravenous administration, and my own experience has satisfied me that it does, in arthritis, it would seem quite obvious that the intramuscular method should be preferred for its simplicity, and greater safety, and ready availability of the antigen. Veins need not be repeatedly punctured. The reaction following the intramuscular milk injections is less violent. I have given it to some patients who had had their arthritis for many months and been much enfeebled with surprisingly good result, considering the conditions, and with no dangerous symptoms as a consequence of the treatment. I well recall an old woman of 73, who had had all local foci of infection cleaned up, but whose chronic infectious arthritis continued (over two years) being markedly improved by this treatment. This senile, emaciated, and much worn patient responded to the injections with the most marked reaction in my experience, yet was able and willing to stand a half dozen injections.

This treatment is properly applicable to all forms of infectious arthritis, including acute, polyarticular rheumatism, but in my experience gives the most brilliant results in gonorrheal cases. Anyone who has had experience with gonorrheal arthritis knows how resistent these cases are to all the older methods of treatment. It is unnecessary to dwell on this at length, and no amount of talking will be as convincing of the marked superiority of the method I am urging, as will a personal trial of it. I want to make it quite clear that my advocacy of this method is not meant to be to the exclusion of other unharmful, adjuvant treatment. Obviously, primary foci of infection about teeth, tonsils, etc., should be cared for. Proper splints, local heat, baking, compresses, diathermia, etc., may aid, and should not be neglected. In chronic, long-standing cases adhesions will not be resolved by this therapy, but these cases should be given the proper mechanical treatment as soon as the injections have reduced the persisting infectious proc-

ess. In regard to gonorrheal cases I want to emphasize the fact that the urethral process should generally be given the very minimum of local treatment. I have preferred to omit everything but the oral administration of urotropin in these cases, and have repeatedly seen the urethral discharge disappear and urine clear up, down to the stage of shreds, during the period of milk injections, and I firmly believe, as a consequence of the milk injections. When all inflammatory processes in joints, urethra, prostate, etc., have disappeared, the residual urethral peeling may then be treated by approved local measures. When I can say that with these measures I have seen a gonorrheal knee of six weeks' duration, plus the associated urethritis, clear up after four injections, given in the course of one week, to a point where the urine that was formerly purulent became clear and contained only a few shreds, while the knee was completely cured so that the leg could be fully flexed on the thigh, and the patient walk with comfort and without a cane, I feel justified in enthusiastically recommending a trial of the method.

I shall now briefly outline the symptoms that have been noted to follow the parenteral injection of foreign protein. This holds for all forms of this treatment, but the symptoms following the intramuscular injection of cow's milk are seemingly less marked in degree.

Within one-half to two hours following an injection the patient has a chill or chilliness of varying degrees of severity and varying duration. This is soon followed by a rise of temperature. Temperatures as high as 107° F. have been noted (and in some pneumonia cases as high as 109°). This hyperpyrexia must be taken into consideration as in itself a possible factor in the cure of the infection. Rolly and Meltzer in 1908[10] concluded that high temperatures have a favorable influence on infections. This factor may be especially significant in gonorrhea, for the gonococcus will not continue to grow at temperatures of 102° F. The "fever treatment" of gonorrheal vulvovaginitis described by Ylppo[11] is very interesting in this connection.

A profuse sweat is apt to follow the fever. There is generally accompanying headache, sometimes very severe, but in most of my own cases rather mild. Backache, generalized pains in limbs and abdomen, nausea, vomiting, and sometimes diarrhea, are not infrequent. The local process in the joints is temporarily aggravated, as noted especially by increase in local pain, and less noticeably by increased swelling and redness. After the disappearance of the chill a leucocytosis appears. This has been found as high as 75,000, but usually is a good deal lower. The increase is largely in polynuclear neutrophiles. It is to be noted that there is no eosinophile increase. At the end of 24 hours the leucocytes are back to normal. Cowie and Calhoun[8] made some very careful studies of the blood changes after the intravenous injection of typhoid protein, and call attention especially to the absence of an eosinophilia, and to evidence of irritation of the hemopoietic tissues, in the presence in the peripheral blood of atypical lymphocytes, of myelocytes, and of nucleated red cells. They found the best therapeutic results to go with the best myelocytic response. The benefit to the patient from the leucocytic increase must be looked upon as not merely a matter of phagocytosis but also a neutralization of toxin.

Mobilization of ferments as a consequence of protein injections is thus spoken of by Jobling in his Harvey Lecture, already quoted.[2] "In experimental animals the intravenous injection of bacteria, kaolin, protein split products, and trypsin is almost invariably followed by more or less marked mobilization of serum protease and usually of esterase. Similar reactions occur in patients after vaccine or proteose, but not to the same degree nor with the same regularity as in experimental animals. The influence of mobilized ester splitting ferment is as yet obscure. In the ultimate analysis, of course, we must turn to ferments of this nature in order to dispose of the invading organism, because it is more than probable that the actual surface of the bacterium consists largely of lipoids, or intimate lipoprotein combinations, for the destruction of which esterase splitting ferments are probably essential."

The kidneys show no constant disturbance.

Thus let it be noted that in contrast with the symptoms of anaphylaxis there is here a rise of temperature rather than a depression, an increased polynuclear leucocytosis but no eosinophilia, and no respiratory disturbances. Furthermore, there is no specificity.

As general contraindications to the use of this method when it is otherwise deemed desirable may be noted marked general asthenia, organic heart disease, hypertension, and pregnancy. I would add that none of these is an absolute contraindication to the intramuscular milk injections, if they are used with caution, by beginning with small doses and keeping the patient in bed. When trouble has resulted from this method, it has generally been in typhoid cases—rarely in arthritis. In the former one must especially guard against bleeding from the bowel, epistaxis, and hemophilia.

In conclusion, this is an attempt, first, to evaluate a therapeutic procedure which in some quarters is sneered at and in others neglected, in both instances without good reason; secondly, to call attention especially to the simplicity and value of intramuscular milk injections in all forms of arthritis, with particular emphasis on gonorrheal arthritis.

INFECTED APICES OF TEETH AND PYORRHEA ALVEOLARIS.

THEIR DENTAL AND SYSTEMIC RELATION.

By ALBERT WESTLAKE, D.D.S.,

NEW YORK.

MEDICAL men expect the dentist to give them inside information in reference to the revelation made by the Roentgen-ray that 79 per cent. of so-called "dead," or technically described as pulpless teeth, have—apparently—infected apices. Why should the extraction of every such tooth be advocated by certain radicals?

The truth is because the infected foramen of the root apex has not been made surgically clean. This is one of the dental sins of omission, and is chargeable to operating technique. The sin of commission is also a factor because in past years the pulps of teeth have been devitalized by the application of arsenious pastes—a slow torturing method. By the time the pulp is devitalized the root canal is thoroughly infected. The pulp is then twisted around a barbed nerve broach and forcibly extracted, thus leaving the foramen clogged with dead tissue as a focus for infection of the pericementum of the root.

When arsenious pastes have been applied to devitalize the diseased pulp which has been exposed by decay of the tooth, there is usually danger from arseniasis some months after the tooth is filled. Superficial necrosis usually follows arsenical poisoning—the radiograph presenting a dark apical area—with recurrent symptoms of periosteitis.

Since the Roentgen-ray has been the order of the day, the medical profession has been handing the dental practitioners so many nutty problems in differential diagnosis that the newly acquired dignity seems to have affected the dentists' perspicacity.

The excellent operation of apiceotomy, the precise practice of ionization and high frequency, and the application of commonsense methods have almost been lost in a maze of exodontia.

Fortunately, professional pride is aroused as modern dentistry functions to corrective details, its successful exponents being grounded in its surgical, pathological, artistic, and mechanical divisions.

Conductive anesthesia is now relieving the dread of the dental operations where the active drill and nerve broaches are to be used—therefore surgical extirpation of the pulp and immediate root filling are within the time limit of one sitting, followed by a permanent crown filling as convenient.

The writer's faith in electrotherapeutics in dental practice is founded on his association with its evolution through early failures to its present manifest success. He had the honor of introducing cataphoresis to the dental profession in 1892. (Electricity; Its Application in Dental Practice, *The Dental Cosmos*, November, 1892, page 887.)

A few pulpless teeth treated at that time are in the mouths of patients at the present writing, the majority, however, are not clinically recordable.

He predicated the claim for the stimulating action of electric medication over drug osmosis in treating periosteitis, pericementitis, and sensitive dentine. He now upholds the contention that ionic medication clots the cells of the pathogenic bacteria of the infected apices and bone sinuses. These virulent bacteria thrive on the organic nitrogen of the surrounding protein. The rapid coagulation by electroylic action renders the bacterial cells innoxious.

The writer does not agree with those who interpret a small dark point presented in a radiograph at the apex of a root to mean that the area is affected to a degree to cause reflex constitutional disorders. The infected area must become definitely circumscribed and show coagulative necrosis before there can be bacterial invasion of the blood stream. (See Fig. 2.)

Clinical history is accepted as of paramount importance in assisting an unconfused Roentgen-ray diagnosis; *x*-ray methods should be standardized.

The patient never complains of a throbbing pain until an abscess is developing, and if the objective tooth does not respond to percussion when the body resistance is lowered—as instanced in "colds," fevers, and fatigue—there is, clinically, no warrant to charge the major disorders of arthritis, sclerosis, neuritis, etc., to a tiny thrombus at the apex of a root.

The medical practitioner who believes that the pathological conditions of the mouth have an important influence on constitutional metabolism

should have a clear understanding of the operative difficulties to be overcome before dental disturbances are mastered.

The conscientious efforts of the dental practitioners, founded on their clinical experience, are directed to standardize the treatments of pyorrhea alveolaris and the filling of root canals because, if the reparative key of usefulness to the adult masticating organs is not found the economic efficiency of our complex civilization will suffer.

The operative technique used by the writer for nerve blocking preliminary to the surgical extirpation of the pulp and the filling of root canals is in some repects, allowing for modifications as the case demands, similar to the office practice of his confrères who favor electrotherapeutics. In many cases local anesthesia of the pulp by ionization is very successful. Immediately following the application of novocain-suprarenin solution, or a similar injection for nerve blocking, the objective tooth is isolated in the usual way. The metal clamp which holds the rubber dam about the neck of the tooth is painted with a heavy coat of chloropercha. When the chloroform evaporates a layer of guttapercha remains which interferes with the diffusion of the electricity used in the application of ionization. The tooth cavity is then flooded with medicated alcohol, and desiccated by warm air. The decayed tooth is drilled until the cavity is shaped for filling —the débris being blown out with compressed air. The pulp chamber thus freely exposed is flooded with iodine, the slight bleeding being wiped out and the cavity again desiccated by medicated alcohol and compressed air, as the object of this second treatment is to expose, macroscopically, the entrance to the root canals which is shown by the remaining iodine stains.

The next procedure is to sterilize the entire track. This is accomplished by zinc ions created by saturating the cavity with a 5 per cent. solution of chloride of zinc and inserting a finely tapered positive zinc electrode into the canals—the negative sponge-faced, salt-soaked electrode being held in the patient's hand on the same side of the body. The degree of current and amount of time needed to carry the antiseptic ions of zinc into the cellular structure of the roots, through to the periapices and possibly beyond depends upon the judgment of the operator, based on experience. The ionic action is more definite if the zinc electrode passes through a moist chloride of zinc field. A steady application of from one to five milliamperes from two to ten minutes usually assures an aseptic track. The removal of the remaining tissue in the root canals by sterilized finely barbed nerve broaches is now a simple operative detail—the danger from mechanical infection having been thus eliminated by the technique. The next procedure is to enlarge the root canals by a sterilized broach reamer attached to the dental engine. This part of the operation must be checked up by reference to the radiograph, showing the relative length of the root. When the operator is satisfied that the apex of the root is nearly reached, the canal is cleansed of its débris by sterilized nerve broaches and the ionization process repeated—this stage of continuous treatment requiring about three minutes.

A finer broach reamer is now carried into the canal and rotated steadily by the thumb and first finger, thus *feeling* its way into the foramen. If the instrument passes slightly through the foramen there is little, if any, additional surgical shock than when the pulp was first dissociated from its main connections.

The canals are now flooded with iodine and the negative zinc electrode is inserted to the extreme apex of the root. Five minutes' application liberates and distributes the stimulating ions of iodine to the periapical tissue.

Clinical experience warrants an immediate filling of the root canals as the pathological recovery is normal, therefore the canals are wiped with medicated alcohol to assist desiccation. A thin chloropercha solution is carried to the apex by a fine nerve broach. Immediately a stiff guttapercha finely tapered point which has been resting in chinosol powder, is rotated the entire length of the root and the canal mouth is sealed with copper cement or copper amalgam, the finishing filling of the crown being a matter of convenience.

After the rubber dam is removed and the mouth is refreshed with a copious irrigation, the gum area over the root is painted with the following solution:

Iodine crystals,	50 gr.	
Potassium iodide,	15 gr.	
Zinc iodide,	15 gr.	
Glycerin,	4 dr.	
Water,	4 dr.	(Skinner)
Menthol,	5 gr.	(Westlake)

An indented glass high frequency electrode placed over the gum conveys the warmth of this high voltage and low amperage current through the tissues. This has a soothing effect because it calls more blood to the parts to counteract the nerve irritation caused by the conductive anesthesia and ionization. A large, smooth glass high frequency electrode may be used with comfort over the periphery of the facial nerves.

Roots do not always grow straight to their apex. Root reamers usually break when forced by engine power through the canal of a curved root, therefore the operator must attempt to feel his way by rotating a hand drill. If this results in failure to reach the foramen, he has but one course open before resorting to root amputation, namely, an attempt to cause a complete mummification by ionization of the remaining fibers in the canal of the curved portion of the root. The result is problematical, because the prognosis can be made only by a time test.

If the root remains comfortable and the apical area appears normal in the radiograph for a period of three months after the canal and crown have been filled, the case may be dismissed. If, however, within thirty days after filling the tooth, it remains slightly sore when tested by percussion and the evident stagnation of circulation of the periapical area cannot be displaced by means of the high frequency current applied over the point of tenderness on the gum, then there remains the operation of apiceotomy, rather than exodontia.

The accompanying radiograph (Fig. 1) shows the root apex area at the present time of a superior lateral incisor after an excision of its infected apex

in 1901. Note the root canal filling. Fig. 2 shows a superior right lateral incisor and an impacted curved root cuspid.

The periapices of the incisor root present coagulative necrosis. These teeth were extracted in November, 1919, and the circumscribed bone curetted. The recovery was rapid as the tissues responded to ionization and high frequency treatments. For two years previous to their extraction the incisor was elongating and the patient presented casts in his urine. In March, 1920, reports showed normal urine.

The focal infection about the incisor and the pressure of the impacted cuspid may have been an *associate* cause of kidney disorganization, for when the diet of the patient was corrected after the extractions the metabolic balance was restored.

From the pathological standpoint root impaction should be considered as vital a factor in reflexes as an impaction in any other part of the economy.

To assist the reader to visualize the percentage of success to failure of ionization and high frequency, the following cases may be selected as typical.

In September of last year 117 cases were presented suffering from pulpitis, periostitis, peri-

FIG. 1 FIG. 2

dontitis—some having exposed suppurating pulps and some with devitalized pulps—all of them texts on which to preach the doctrine of dental hygiene. In December following 102 on the list showed normal apices and useful teeth. Fifteen failed to respond to treatments, so four were extracted and eleven roots were resected—showing normal tissue recovery at the present writing.

Pyorrhea Alveolaris.—The sufferer from diseased gums often presents excellent tooth structure with few, if any, decayed teeth.

Observation has proven that a male from 19 to 25 and a female from 16 to 21 whose gums show a line of redness about the gingival margin will be victims of the disease of pyorrhea alveolaris before fifteen years pass unless they follow the vigilant rules of oral and body hygiene.

The medical profession may be assisted in their diagnosis of metabolic disorders by the above statement, and a lead may also be had if the gums show a recession without pus pockets, exposing a smooth, shiny neck of the root. This latter affliction indicates to the dental diagnostician a uratic diathesis and a tendency to arteriosclerosis.

In the writer's 32 years of active office, clinical, and hospital experience, he has never handled a true pyorrhea case where the patient did not show a weak peristalic action of the intestines and consequent autointoxication. In a large percentage of cases the patient suffered from hemorrhoids.

The urinary report of a typical subject shows indican and the feces analysis presents hydrobilirubin. Shreds of meat and vegetable fibers are visible macroscopically. Urobilin and urobilinogen are evident. Starches show in greater or less amount according to the extent of the pyorrhea. With such an upset of the pancreas and bile glands the function of the enzymes and protective protein in the blood stream is curtailed.

Excess amounts of orange pigments are set free in the current and their toxic effects are noticeable at the anatomical terminals—such as the gum festoons where local irritants of serumal or salivary calculus have obstructed circulation.

Palliative treatment of pyorrhea alveolaris is useless. The surgical technique used by the writer is to open the gum down to the base of the deep-seated pocket and curet smooth the exposed serrated edges of the alveolar process. This incision exposes the affected side of the root from which all calcareous deposits are removed.

After a thorough removal of these deposits and the resection of the necrotic alveolus, the parts are freely irrigated with a warm saline solution and the iodine and iodide compound, previously described, is freely painted on the gums and around the teeth.

This is promptly followed by the application of a smooth-faced glass electrode dipped repeatedly in a saline solution to convey the high frequency current as an analgen. The patient is dismissed for three to five days with instructions to use a mouth wash and a dietary schedule. The gums are sensitive and bleed easily, therefore the diet is mainly gruels, milk, eggs, cream toast, marrow, and associated soft food.

Naturally the tooth brush is looked upon with dread, therefore a substitute is suggested. A piece of cheese cloth or cotton rolled on the finger may be used or the skin of an orange or lemon. A strip of skin of the grape fruit is an excellent abrasive used as one would a stick of sugar cane or an orange stick.

As mouth washes of alcohol and essential oils do not cut the mucin and fatty deposits from the teeth and gums the patient must call for an automatic remedy. Under these conditions there is nothing equal to citric acid juices. Lemon, orange, or grape fruit juices dissolve the mucin plaques and when followed with a glass of clear water complete a perfect irrigation. Citric fruit juices are especially effective if the skin and pulp are crushed together in a porcelain bowl, as in that way the vitamine, antiscorbutic, and antineuritic elements are retained. The gums soon present a clear light pink appearance which seems to substantiate the claim that citric fruit juices have an antipyretic action. The usual proportion for a wash is about five parts of water to two of fruit juice. The reason why lemon juice "sets the teeth on edge" is because its action cleans the mucin plaques from the teeth. The alkaline saliva is automatically stimulated by fruit acids.

At the next office appointment the treatment is

palliative. A glass-indented electrode in which has been placed a small piece of cotton saturated with a solution of five parts of sodium chloride to two parts of chinosol is applied to the gums and a snappy amount of high-frequency current is used to stimulate circulation. Concurrent use of ionization is sometimes demanded when obscure pockets develop—especially where the patient's condition is influenced by congenital or acquired lesions.

In the presence of incipient pyorrhea the studied application of ionization and high frequency usually accomplishes satisfactory results.

When about to dismiss the patient, a thin pencil-marking of nitrate of silver is made around the tooth at the gum margin, thus leaving an albuminate of silver which is not only a marking in case further recession occurs but in many cases is a curb to bacterial nests.

The dentist can restrain the decay of teeth, diseases of the gums, and the infected areas of some roots, but these inhibitory treatments do not insure immunity from recurrence if dental and body hygiene are neglected.

While the physician is studying the medical pathology of the patient, the use of a fruit laxative is suggested as an emergency correctant which not only acts as mildly operative, but has a favorable metabolic action in severe pyorrhea cases.

One-half pound of prunes, pitted, chopped fine, and soaked; ½ lb. of figs, chopped fine; 5 teaspoonfuls powdered senna, 1 cup New Orleans molasses.

Simmer for five minutes, pour into a Mason jar, and keep in a cool place.

Dose: 1 to 3 teaspoonfuls at night, as required.

After the morning and evening meal the patient drinks the juice of two or three oranges and one lemon. Part, at least, of the skin should be crushed with the pulp, because it is accepted as carrying the vitamine content. This drink, after eating, appears to have direct action on the endocrine secretions as indicated by their stimulation, due doubtless to the rapid distribution of the natural organic salts of the fruit. In some cases the physician has recommended yeast treatments, which appear to have beneficial results.

Every dentist who has been in active practice for twenty years or more knows from observation that decay of teeth and diseases of the gingiva are constitutionally associated with destructive metabolism. Decay of the teeth and pyorrhea alveolaris are primarily due to either a congenital or an acquired defect in the glandular cooperation of the individual, which has resulted in mineral catabolism. It is not true that "a clean tooth never decays." Many an individual who has never used a tooth brush will show a perfect set of teeth.

We are not required to go back to the aborigines to prove that statement. This statement may hurt the feelings of some masters of the unclean tooth brush drills. It may awaken them, however, to be diligent in the crusade to correct the "wholesale" method of cleaning teeth and enroll them as teachers of the truth that each tooth and gingiva must be cleaned with the same care as is bestowed upon the individual nail of the fingers, once daily—at least until the evolution of an improved race, who will use clean cotton or a similar product rolled on the individual finger to massage each tooth.

The progressive dentist who believes in preventive measures as evinced by his active indorsement of the great oral hygiene movement also believes in child hygiene. Both promise an evolution to standardized methods which assure a physically and mentally improved race. Therefore, the care of the young generation as the prospective parents calls for a closer association of the physician, dentist, and dietician who believe not only in calories but in the anabolism of the mineral constituents of food brought about by a normal endocrine balance.

The statement that 30 per cent. of the children are born with a pilary sac in the anal structure coincides with the observation of the writer that those who have no rectal defects or whose contracted sphincters have been corrected show a better dietary record and tooth structure than those who suffer from delayed exit of cecum-colon waste.

The first fifteen weeks of gestation are the important periods in which the dentist is interested. During this period the endocrine balance of the future mother should be carefully considered, the parathyroid and thyroid having a marked control over mineral anabolism.

The sphenoid is considered an important bone by the dentist, as its foramina allow the passage of the nutrient vessels to his anatomical workshop. Normal functioning of the pituitary gland in its fossa is important for the mouth welfare of the mother and her offspring.

About the fifth week the face portion begins to form, as does the enamel germ of the first tooth, and within the ninth week the lips and nose. The premaxillary bone which holds the six front teeth also assumes its contour and about the twelfth week the roof or hard palate should be uniting on both sides of the arch. This is closely followed by the corresponding lower jaw.

The arches or bow-like curves of the jaw are thus shaping in unison with the other bones of the head, their junction being perfect unless there is a recession of type.

When cases of cleft palate and congenital deformities are brought to the dentist he is influenced on general principles to charge the abnormality to atavism rather than to agree with the maternal contention of prenatal shocks, but when certain members of a family—raised in the same environment—have pyorrhea and sound teeth, and their brothers and sisters have decayed teeth and healthy gums, the truth is forced home that endocrine cooperation, which is coefficient with a normal anatomical exit for intestinal waste, are vital factors in maintaining a completeness of dental balance.

500 FIFTH AVENUE.

Some Spanish Health Statistics.—A recent number of the *National Health Bulletin* of Spain has caused Rodriguez to be somewhat pessimistic of the governmental control of disease. Last July the number of births in the provinces was 39,091 and in the capitals 6,755; total, 45,846. The total number of deaths for the same period was 49,328. There is, therefore, a deficit in natality of 3,482 in a single month. During the latter half of 1919 there were 2,568 deaths in Spain from typhoid fever and 1,778 from smallpox. In the first half of that year there were 18,134 deaths from tuberculosis. The total mortality in six months from preventable diseases was 62,973.—*El Siglo Medicó.*

KIDNEY FUNCTION IN A CASE OF BICHLORIDE POISONING.*

By HERMAN ELWYN, M.D.,

ASSISTANT VISITING PHYSICIAN, GOUVERNEUR HOSPITAL, AND INSTRUCTOR IN MEDICINE, COLUMBIA UNIVERSITY,

AND

EDWARD P. FLOOD, M.D.,

NEW YORK.

MARY A., Italian by birth, aged 18, was admitted to Gouverneur Hospital, service of Dr. C. N. B. Camac, February 15, 1920, with the diagnosis of bichloride of mercury poisoning. She had been in the hospital before, from February 11, 1918, to March 4, 1918, for bichloride of mercury poisoning, and was discharged as cured. She had been only moderately sick, had blood in the urine for the first few days, a slight amount of albumin with a few casts. She never had any anuria and her blood pressure ranged from 104 to 140 systolic.

Present History.—Sunday, February 15, 1920, the patient swallowed three tablets of mercuric chloride, 7½ grains each, with suicidal intent. Within ten minutes she experienced severe pains in the stomach. She then told her mother what she had done. Her mother called a policeman and an ambulance. The policeman gave her milk and raw eggs to drink. The ambulance surgeon washed her stomach for twenty minutes. On admission to the hospital she complained of severe abdominal pain and soreness of the mouth and throat.

Status on Admission.—Her appearance was that of a well developed young white woman, rather pale, with an anxious expression, evidently suffering from abdominal pain. Her eyes were negative, pupils reacted to light and accommodation. Her mouth and tongue were slightly congested. The heart and lungs were entirely negative. The abdomen showed slight tenderness on pressure in the epigastrium. Her extremities were negative, reflexes normal.

Course.—She was not able to void any urine on admission, and none was obtained on catheterization. Her anuria persisted for three days. On the fourth day, four ounces of bloody urine was obtained. The urine was alkaline, of Sp. Gr. 1012, contained a heavy precipitate of albumin, a few granular casts, many white and red cells. Her blood pressure was 125 systolic, and 95 diastolic. She developed a marked stomatitis. Her gums were swollen, the mouth covered with white patches with areas of necrosis on the right margin of the tongue. She vomited considerable quantities of blood and also had numerous bloody stools.

She was placed on treatment as recommended by Lambert and Patterson,[1] including stomach washing twice a day, colon irrigation twice a day, and imperial drink by mouth. A solution of potassium acetate, one dram to a pint, was given continuously by the drop method of rectal irrigation. She also received a daily sweat in a hot pack.

Improvement was gradual. On February 23 the non-protein nitrogen was 265 mgm. per 100 c.c. of blood Her urine contained many red and white cells and a very heavy precipitate of albumin. She voided 12 ounces of urine that day. On March 1, 19 days after ingestion of the poison, she passed 80 ounces of urine. No red cells were found, and there was a faint trace of albumin. Her phthalein output for the first two hours was 5 per cent. On March 2 her phthalein output was 22 per cent. for the first two hours, and her non-protein nitrogen was 115.7 mgm. per 100 c.c. of blood. On March 4, 22 days after ingestion of the poison, the patient voided 40 ounces of urine Sp. Gr. of 1010, with a faint trace of albumin. Her blood count was as follows: Red cells, 1,376,000; hemoglobin, 30 per cent.; white cells, 7,600; polynuclears, 68 per cent.; lymphocytes, 14 per cent.; transitionals, 4 per cent.; large mononuclears, 3 per cent.; eosinophiles, 10 per cent.; mast cells, 1 per cent. March 6, her phthalein output was 25 per cent. for the first two hours, and 60 per cent. at the end of four hours. Her non-protein nitrogen was 43 mgm. per 100 c.c. of blood. March 9, her red cell count was 2,408,000, and hemoglobin 44 per cent. Sahli. Her fluid intake was 80 ounces, and she voided 60 ounces of urine. On March 11, her non-protein nitrogen was 30.7 mgm. per 100 c.c. of blood. Her fluid intake was 50 ounces and her urine output 60 ounces. The urine contained a faint trace of albumin, was alkaline, and of Sp. Gr. of 1014. Her phthalein output was 42 per cent. in two hours.

By this time her mouth had gradually improved. There was no bleeding any more, either from the mouth or from the stomach, and there was no blood in the stools. On March 12 both stool and urine were negative for mercury. On March 16 her blood count was 2,800,000, with hemoglobin 60 per cent. Sahli. The urine still contained a very faint trace of albumin. Phthalein output was 45 per cent. in two hours. She was discharged on March 19, feeling perfectly well.

The case is presented with a view to illustrate the pathological physiology of the kidney in bichloride poisoning. The bichloride kidney presents definite anatomical lesions which must be brought in correlation with the change in function. It has the advantage over other kidney lesions in that no other general mysterious metabolic disturbance need be assumed, such as is the tendency now to assume as a cause for other kidney lesions.

In a previous paper one of us[2] has attempted an explanation of the pathological pysiology of the kidney based on Cushny's modern theory of kidney secretion. Using at the same time the classification of renal diseases into tubular degeneration, glomerular inflammatory, and vascular sclerotic lesions. Briefly, it was as follows:

The glomeruli filter a deproteinized plasma, the tubules reabsorb the water and most of the threshold bodies, thus concentrating the rest of the urinary constituents. Filtration is dependent on pressure supplied by the heart, and the flow of blood to the glomeruli is regulated by the play of the vasomotors, which is extremely sensitive in the kidney. The kidney has no secretory nerve fibers.

When the glomeruli are inflamed there is a hindrance to filtration and the body attempts to maintain the filtration by increasing the pressure. In proportion as the body is able to maintain it, function will be maintained. An index to maintenance of function is given by observing the rest nitrogen level in the blood or by observing the individual non-protein constituents of the blood, such as urea, uric acid, or creatinine. The level in the blood of these substances will vary with the severity of the glomerular inflammation, the ability to call the mechanism of hypertension into play, the ability, by means of the increased pressure, to force blood through the inflamed glomeruli, and the ability to maintain the mechanism of hypertension until glomerular inflammation has subsided. What the actual mechanism in the production of hypertension is, we do not know. We can only say that the stimulus which calls for increase in blood pressure must arise from the small arterioles in the kidney and from the glomeruli, or the vessels leading to the glomeruli, as it is these vessels when inflamed or when sclerosed which call the mechanism of hypertension into play.

In tubular affections when the glomeruli are not involved, kidney function is maintained. There is no increase in rest nitrogen and no increase of blood pressure. Disturbance in function manifests itself by the permeability of Bowman's capsule, which

*From the Medical Service of the Gouverneur Hospital, New York.

forms the beginning of the tubules, to the proteins of the blood, and by the formation of casts.

In bichloride of mercury poisoning there seems to be an apparent contradiction to the above explanation of kidney function in disease. The following is an attempt to clear this up:

The bichloride kidney has been classified by Volhard and Fahr[3] as a "Necrotic Nephrosis" or as a "specifically characterized nephrosis" ("bestimmt characterisierte Nephrose"). The pathologic anatomy has been carefully studied by Heinecke,[4] Leutert,[5] and others, and is well known to pathologists. It consists of a necrosis of the proximal convoluted tubules of the kidney, involving most intensely, according to Suzuki,[6] the first part of the convoluted tubules and the fourth part where it joins the descending loop of Henle, and to a lesser extent the second and third part. The ascending loop of Henle and the distal convoluted tubules are also effected but to a less extent. Calcium is deposited in and around the necrotic cells. There is regeneration of the cells of the tubules with a throwing off into the lumen of the tubules of the necrotic and calcified cells. There is also some interstitial infiltration with edema and swelling of the whole organ. The glomeruli are not affected. There may be at times slight congestion and at times there is a fine sprinkling of fat droplets on the capillaries of the glomeruli.

As the glomeruli are not involved we should not expect to find any signs of kidney insufficiency. The only signs we would expect to find would be the presence of albumin and casts in the urine. How, then, are we to explain the anuria, the increase in the rest nitrogen level, and the presence of blood in the urine? Why, if there is an increase in the rest nitrogen level, does not the mechanism of hypertension come into play?

Hematuria.—The presence of blood in the urine is practically a constant find in the early stages of bichloride poisoning. Yet in studying the plates of the above-named authors and on viewing sections of bichloride kidney no red cells are found in the capsular space. It seems to be a rational explanation that the blood in the urine in bichloride kidney poisoning is not at all derived from the glomeruli, which are not inflamed, but is probably derived from the capillaries of the necrotic tubules.

Anuria.—The anuria is one of the most difficult things to explain in the bichloride kidney. As the glomeruli are not inflamed there is no reason why their function should cease, yet anuria or oliguria is practically a constant phenomenon in the bichloride kidney, and death is very often a consequence of the anuria. How then are we to explain it? We believe the following threefold cause explains it: First, the swelling and edema of the kidney stretches the capsule to its limit and compresses the larger vessels in the kidney, resulting in a diminution of the blood flow to the glomeruli with a lowering of the filtration pressure in the glomeruli. The lessening of filtration is in all probability aided by the choking of the tubules with the débris of necrotic cells. That the first factor is important can be inferred from the recovery of patients who have had the kidney capsule incised. There is probably also a third factor, namly, a reflex constriction of the vessels of the kidney produced by the insult to the kidney and reflected by the very sensitive vasomotor system.

Rest Nitrogen.—The increase of non-protein nitrogen has been a constant observation in cases of bichloride poisoning ever since blood studies on such cases have been attempted. Such studies have been made by: Campbell,[7] Lewis and Rivers,[8] Underhill,[9] Meyers and Lough,[10] Rosenbloom,[11] Foster,[12] Woods,[13] Meyers and Fine,[14] and others. Among the cases reported there is none with such high figures as in our case, namely, 265 mgm. per 100 c.c. with recovery.

Campbell's first case, which recovered, had 232 mgm. per 100 c.c. with 12.5 mgm. of creatinine, which, according to Meyers and Fine, is indicative of a fatal outcome. Underhill's case with recovery had 240 mgm. of non-protein nitrogen per 100 c.c. Lewis and Rivers report 184 mgm. per 100 c.c., with recovery.

This is in marked contrast to the cases of glomerular inflammation where a rest nitrogen level of above 200 mgm. is usually indicative of a fatal outcome, and where Meyers and Fine's dictum of the prognostic value of creatinine unquestionably holds true. The explanation for the benign character of the increase in rest nitrogen is, that the rest nitrogen must be considered solely as a function of the anuria which results from the causes mentioned above.

With a subsidence of the edema and swelling of the kidney, and with the relaxation of the constricted vessels, filtration is at once resumed, and the rest nitrogen level sinks with remarkable rapidity. The published cases show this clearly. In our case the rest nitrogen sank from 265 mgm. to 30.7 mgm. in 17 days. In Campbell's case it sank from 232 mgm. on February 18 to 48 mgm., on March 9, and to 30 mgm. on April 11. In Rosenbloom's case it sank from 176 mgm. to 60 mgm. in 7 days, and to 23 mgm. in 13 more days. In Lewis and Rivers' case, from 170 mgm. to 26 mgm. in 8 days.

That the increase is due to the anuria is also shown by Campbell's second and fatal case, in which all the constituents were equally increased, namely, total protein nitrogen, 319 mgm.; urea, 200 mgm.; blood sugar, 0.46 per cent, and creatinine, 21.3 mgm., per 100 c.c.

We can easily infer from this, that the rest nitrogen increase is due to the anuria and not to the alleged diminished secretion through the diseased tubules. The reduction of the rest nitrogen on improvement is entirely too rapid to allow for sufficient time for regeneration of the tubules.

Blood Pressure.—In our case, the blood pressure was 125 systolic on admission and ranged around 110 systolic and 70 diastolic. In the published cases cited above, the blood pressure is often not mentioned, and when stated, it is evidently normal or only very slightly increased. The experience of many clinical observers has been that at times the blood pressure is increased, especially later in the course. Janeway[15] remarks that it is sometimes increased early in the course. However, this is not a constant observation, and it always returns to normal on improvement. In Campbell's first case, with 232 mgm. of rest nitrogen, the blood pressure was 110 to 120 systolic, and 80 to 95 diastolic. Campbell's second and fatal case had a blood pres-

sure from 130 to 140 systolic and 70 diastolic. In Foster's fatal case it was 100 to 140 systolic.

Why, then, does not the mechanism of hypertension come into play? As this would, if effective, possibly cause filtration to continue, and lower the level of the excretion products in the blood. Of course we are not, in the present state of our knowledge, in a position to give a definite answer to this question, but we can rightly infer that a stimulus for hypertension must in some way originate from the glomeruli or the small kidney vessels, when these are affected. These are not affected in the bichloride kidney, and only at times with perhaps a continual diminution of blood in the vessel is the stimulus for increased pressure aroused. That hypertension is produced when the glomeruli are diseased can be seen in any case of acute diffuse glomerulonephritis where the blood pressure has previously been known.

We wish to call attention to another point in our case. On March 4, our patient had a blood count of 1,376,000 red cells, with 30 per cent. hemoglobin. The anemia was without question partly due to the loss of blood by mouth and rectum. But the increase to 2,408,000 red cells with hemoglobin 44 per cent. within five days, and after passing large quantities of urine, leads us to believe that there was a true hydremia. The patient had received from the beginning large quantities of water with the Lambert and Patterson treatment, and had hardly passed any urine at the beginning. With the restitution of filtration, this extra amount of fluid was promptly excreted.

Summary.—We understand the pathological functioning of the bichloride kidney to be somewhat as follows:

1. With the insult to the kidney, the tubules are necrosed, desquamated, and fill the lumen. The kidney is swollen, the capsule is tense and constricts the vessels. There is also possibly a reflex vasoconstriction.

2. This causes anuria. Consequently all excretion products in the blood are retained and the level of the total non-protein nitrogen and of the various non-protein constituents rises.

3. As the glomeruli or small vessels are not diseased, the mechanism in producing hypertension is not called into play, or only slightly and in the later stages.

4. With the lessening of the swelling of the kidney, and the relaxation of the constricted vessels, filtration at once is resumed and the retained excretion products are rapidly removed.

5. Bowman's capsule has become permeable to the proteins of the blood, which appear in the urine; these also coagulate and form the ground substance on which various cells are deposited with the formation of casts.

6. The blood in the urine originates in all probability from the bleeding capillaries of the necrotic tubules.

THE MENTAL COMPLEX.

By H. Laveson, M.D.,
New York.

Complex is a name given by psychoanalysis to an idea or a group of ideas with which is associated a tone of unpleasant feeling which keeps or tends to keep the complex out of consciousness. The difference between the complex and the ordinary forgotten occurrence is that the latter has no feeling tone connected with it when it occurs and therefore does not have the energy, so to speak, to form a connection with other registered experiences, or life to go on developing by the assimilation of other experiences. Thus every experience which arouses at the same time a pleasant emotion is welcomed again and again into consciousness. We like to recall what pleased us. On the other hand, we know that we do not try to recall unpleasant events. That a recent unpleasant event tends for a time to keep recurring to our minds is an example of what might be called an emotional after-image, and gives us the opportunity of working off the unpleasant event spiritually by consciously arranging it in our minds and finally disposing of it. It is only the unpleasant events which, crowded out of consciousness by our fear to face them as adult humans, should carry with them into the unconscious the emotions which are the life of ideas and allow that life, like the sickly growth of pale plants in a cellar to develop uncared for by the consciousness. It is natural that we should remember the pleasant and forget the painful. But the pleasant occurrences being frequently evoked and talked over with our friends, are brought into alignment with our daily conscious lives. They give us strength for our present and inspiration for our future tasks. They do not become associated in a lump in some corner of our minds, but are connected with all our friends, telling them things they want to know. A pleasant adventure makes us friends with everybody. How much more sociable are strangers when on a holiday in the mountains or at the seashore! The travel or adventure is unfolded or explicated, so to speak, and acquires relations with all of our mental life and so does not become coagulated or tangled up in one bunch.

A complex, on the other hand, being repressed into the Unconscious on account of the painful feeling connected with it, at once begins in the Unconscious

to associate with itself a number of other ideas, all of which take on the unpleasant quality. These ideas, therefore, are prevented by this acquired unpleasantness from coming into consciousness. The person in whose mind these complexes are forming will not, without an effort, be able to remember these ideas when he wants them. The complexes will detach from the foreconscious, where are stored the ideas which are subject to voluntary recall, one person's name, another person's address, another's occupation, and drag them down toward the Unconscious, where they will nevermore be subject to his will. It is thus seen that, when looked at from the under side—as it were, from the point of view of the Unconscious—there must be complexes forming down there from the time of our earliest infancy. The complexes continue to develop and attach more and more ideas to themselves until finally our minds, even those of us who are completely normal, are made up of an overwhelming majority of forgotten or repressed matter, all of it available for the purpose of feeding the complexes, and none of it of any use to ourselves. Only the fullest human lives can prevent this formation of a sodden mass of complexes in the Unconscious of every one of us. The experiences of a thoroughly unsuccessful and disappointed life keep on making for oblivion, drawing one event after another back into the unconscious part of our psyche. The most active and successful men and women, therefore, will, other things being equal, have the fullest memories, will be able to converse most entertainingly, for they will have the fewest complexes as inhibitious on their mental life, whether that mental life be expressed in words or in actions.

Any indication that reveals the working of the complex is called a complex indicator. In the tragedy of "Hamlet" that part of the play within the play where the murder takes place produces the effect upon Claudius of making him leave the room in confusion. His confusion indicated his complex, which was caked about his own guilt, and was his complex indicator. In the association experiments, where a number of words are given to the subject and he is told to utter the first word that occurs to him, the hesitation he shows in associating with some of the words is his complex indicator, and the word that caused that hesitation is invariably found to be connected with some complex. It has called up some unpleasant memory which he wishes to forget or is unwilling to publish; and his hesitation is caused by his trying not to say the word which spontaneously comes to his mind, for fear it will betray him, but to think of and say another. Any hesitation, therefore, is likely to be a complex indicator, except in the case of people who intuitively know this, and such people often betray their complexes by an unexpected or inappropriate fluency or glibness.

It sometimes happens that there is in a given individual only one obvious complex. We all know people who are a "little bit off" in one respect but are conventional in their actions in every other. The eccentricities of genius as well as of ordinary persons are examples. Other persons' peculiarities, such as an inability to touch certain substances, velvet, silk, cotton, etc., or a diet consisting of rock salt, molasses and butternuts, or a refusal to eat anything with raisins in it, or a belief that some special kind of food is impossible, like strawberries or cucumbers, all of these are eventually traceable to complexes. It is well to remember that the complex is always based on unconscious thoughts, and that the reasons given by the persons are not ever the real causes of these eccentricities. Most of them are connected with intimate attitudes toward the ideas not merely of nutrition but of reproduction.

The man who could not eat food containing raisins explained his dislike of them by saying that he judged all tastes by the feeling of the food in his mouth, that raisins felt like insects, and that he really liked soft and tender foods, in spite of the fact that he had a good set of teeth. The upshot of it all was that he showed an unconscious tendency in the direction of breast milk, in other words was, while a man in stature and years, only an infant in this characteristic, which, indeed, as the analysis progressed, was found to be paralleled by infantile traits in other spheres of life. Thus he made a demand upon his wife for an expression of tenderness of a kind that should have been expected only from his mother. He showed, too, an attitude toward the world which evinced in him an expectation that it would give him things, not that he should force things from it or even win them by his own efforts. This was side by side with traits that enabled him to do acceptably the tasks imposed upon him by his business, and to be taken by his acquaintances for a man in most other respects.

The Oedipus Complex.—The Oedipus myth has been used in psychoanalysis as a measure by which to test the relative development of the individual psyche. By means of the interpretation of a given person's dreams it is possible to tell how far his Unconscious has progressed along the line of evolution from the place where it desires the possession of the mother above all else in the world. It is shown by this method that the psyche of a great many persons afflicted with certain sorts of nervous disorders has been subject to a fixation upon the mother. This applies, in strict literalness, of course, only to men. But the corresponding unconscious mental state occurring in women is quite as common if not more so, and is sometimes known by the name of the Electra complex. A complex is a group of unconscious ideas, or, rather, a group of ideas in the Unconscious, which, having been subjected to repression, continues to have an independent existence and growth. The Electra complex is for women quite analogous to the Oedipus complex in men, so much so, in fact, that the name Oedipus complex is indifferently used for both, the relations to be changed being understood. Thus, as the primary affection on the part of the boy is for his mother and his earliest wish is to supplant the father in the affection of the mother, so the primary affection of the little girl is for her father, and she wishes above all things to supplant her mother in the regard of her father.

The Small Penis Complex.—Little boys of say four or five years of age, when passing through the period of sexual investigation are often profoundly impressed with the difference in size between their own organs and those of grown men, the older brother or the father. From these comparisons

arise a feeling of envy and jealousy and also a sense of inferiority, and this forms a nucleus for a complex which grows and persists long after the impressions with which it started have faded from conscious memory.

The Mother Complex.—In regard to the fidelity which our reactions bear to early impressions it might be said that we resemble certain primitive races, such as the Bushmen of Australia, who have practically no abstract words or ideas. In place of such a word as hard the savage thinks like a stone; long is like a river; blue is like the sky. In the same way, to our unconscious thinking, Miss Jones is not beautiful, amiable, or sympathetic, nor Mr. Smith overbearing, quick tempered, or in the way; but like mother, like father, or like brother or sister, as the case may be. But in a certain sense neurotics, and to a less extent all of us exceed the limits indicated by this feature of savage thought and language. The savage's idea of a path which is long may be like a river but he does not act toward the path as if it were a river, and, for instance, try to swim in it. Yet the qualities such as beauty in a woman or overbearingness in a man which to the Unconscious are like Mother or like Father, leads us, within certain limits, to feel, and even to act, as if the case were not one merely of like, but more or less completely, of is. For example, a wealthy young man became infatuated with a divorcée considerably older thar himself, who, as was clearly apparent to every one but him, was a thoroughly unscrupulous adventuress. But in his eyes she was the purest, truest, and best of all women. His friends who tried to save him from her clutches by bringing forth evidence from her past record or present behavior to show that she was absolutely mercenary, were to his mind but slanderers made malicious through envy of his love. He confided to her all his intimate affairs, allowed her to extract large sums of money from him on the flimsiest of pretexts, and put himself absolutely in her power with childlike trust in her being heart and soul devoted to him. The explanation is that certain features of this woman, her being older, having belonged to another, her treating him like a small boy, these, together with some vague similarities in appearance, caused an unconscious identification with his mother, whereupon the whole motor pattern corresponding to the mother-image was brought into play, and he experienced toward her all the feelings of love, trust, and devotion which had been felt toward the actual mother, but which, as anyone but himself could clearly see, were pitifully inappropriate here.

Reactions from the father complex are exemplified in the case of a male patient, an able and fairly successful professional man of considerable wealth and social standing, who complained of often being overawed by persons who, in many cases his reason told him, were really beneath him. If a loud-voiced, aggressive man made a statement, the patient was impelled to agree with him even when he knew the other to be wrong. When a street-car conductor would shout roughly: "Move up forward!" he would feel constrained instantly to obey, even while he realized that perhaps nobody else in the car was paying the slightest attention.

511 East Eleventh Street.

CONCERNING THE TREATMENT OF INFLUENZA.

By DAVID GREENBERG, M.D.,

NEW YORK.

ASSISTANT IN PATHOLOGY, ADMITTING PHYSICIAN, AND CHIEF MALE MEDICAL CLINIC, LEBANON HOSPITAL.

Our experience with influenza for these past two years was such that we may expect it to be an important factor in both the morbidity and mortality of the community for the next few years. While the 1920 epidemic was of a much milder and of a less extensive character than was the epidemic of last year, it was sufficiently widespread to make us fear possible recurrences of this disease, of perhaps a milder degree of severity, in the near future.

So-called influenza has been endemic in the United States for many years, particularly here in the East. With our present knowledge as to the uncertain etiology and variable symptomatology of this disease one may assume an even greater incidence of influenza, but unrecognized in normal times. The past two years have afforded an opportunity for more extensive observations, and yet we have not learned all we ought to know about this subtle infection. Despite the abundance of material, the etiology remains indefinite. Some investigators still report the frequent isolation of the bacillus of Pfeifer or the occurrence of a diplobacillus or coccus in the sputum, lungs, blood, or other tissues. There is, however, nothing approaching uniformity in these findings and most of them lack corroboration. This state of semi-confusion exists not only so far as etiology is concerned, but is also evident when the treatment of this disease is considered. The great number of cases, with the consequent opportunity for intensive study, especially in institutions and in hospitals, has not resulted in bringing forth any therapeutic specific. Early enthusiasm for vaccine and serum treatment have become less marked, judging by the recent literature.

Nevertheless, while we cannot boast of having materially aided in clearing up the etiology or in having discovered a specific in the treatment, we need not be discouraged altogether. Few, indeed, are the diseases, even when the etiology is beyond question, where we have specific remedies, and the search for specifics is not quite so acute now as it was some few years ago. However, poor as we are in specifics, we have established rational treatment for most acute diseases where our efforts are directed toward ameliorating distressing symptoms and toward supporting the patient while he is combating an infection or toxemia. This much we can do in influenza.

The treatment of influenza may, therefore, be said to consist in general measures largely directed toward placing the patient in the most favorable conditions where he may best hope to overcome the invading host, and these are: (1) Absolute rest, (2) fluids, (3) alkalies, (4) nutrition and elimination, (5) counterirritation, (6) drugs.

Absolute Rest.—It seems almost superfluous to mention the importance of rest in bed during the entire course of influenza, as well as during the immediate convalescence. Yet when it is realized how difficult it is at times to keep a patient in bed

after the first 24 to 48 hours, *i.e.* after the first rise of temperature and feeling of general malaise, it is obvious that rest in bed must be emphasized. Even the attending physician, seeing the patient on the second or third day after the onset and finding him practically nonfebrile, and perhaps asking for food and for permission to get out of bed, is apt to yield, thus depriving his patient of a possible means of preventing complications. In the light of our experience it is advisable that patients, suffering from what is clinically influenza, remain in bed for at least five days after the temperature has been normal and there have been no other signs of illness.

And by rest is meant complete rest in bed, without getting out for bathroom purposes. Sitting up and straining at stool certainly is unadvisable for one afflicted with influenza, who may soon need all his reserve energy during a complicating pneumonia. Should there be any difficulty in making the patient move his bowels in bed a simple enema will usually solve the problem.

While in bed the patient should be kept away from visitors and other sources of excitement by proper isolation. He should be given an opportunity to sleep as much as he can or at least rest undisturbed. It is hardly ever necessary to awake a patient for medication.

Fluids.—Early in the epidemic of last winter (1918-1919) when the treatment of influenza first came up for discussion someone from the Naval Hospital in New London reported excellent results from the ingestion of large quantities of water, and emphasized its beneficial effects in most acute infections. I became an early convert to this method of treatment. Whenever I could get the cooperation of the patient and nurse I pushed fluid to the limit, some patients taking as much as 5 to 6 liters of fluid in 24 hours in the first three days of illness, with apparent good results.

It matters little as to the kind of fluid taken. Tap water, orangeade, lemonade, broths, diluted and fermented milk, strained cereals, may be given freely. The addition of fruit juices to a weak lemonade or water helps to break the monotony of the frequent drinking. The large quantities of fluid aided free elimination and helped indirectly in reducing the temperature.

Alkalies.—The recent work done on acidosis and particularly the acidosis associated with acute infection led me to try the administration of large quantities of alkalies in all acute infections as ordinarily met with, such as tonsillitis, acute pharyngitis, bronchitis, and articular rheumatism. In a general way the administration of alkalies seemed to react favorably on the course of these diseases.

There are no definite figures as to the effects noted. (There is very little in the literature about alkaline treatment. Dever and Mure in January, 1919, in their report on the influenza epidemic in the United States Naval Hospital in League Island casually mention liquor potassii citratis.) However, I was so well impressed with my early cases in this epidemic that this alkaline treatment was pushed about in the same way as it is in some forms of pyelitis and acidosis. Most of the cases showing early signs of toxemia, such as extensive pallor, great weakness, apathy, and cerebral clouding, with or without high temperature, were given 2 grams of sodium bicarbonate every two hours with apparently good results. Other alkaline drugs, such as potassium citrate and potassium acetate, were also used in combination with the bicarbonate. The urine was tested repeatedly and if not definitely alkaline when freshly voided, alkalies were increased.

Alkalies and fluids were often given by rectum, especially when there was evidence of nausea or vomiting. This nausea occurs rather more frequently than one would expect. The quinine, which was often used in these cases, may have had something to do with it. It would certainly be worth while to study the various symptoms referable to the gastrointestinal tract with a view to determine the relationship between the frequency of these symptoms and the drugs used. It seems to me that the large quantities of fluid together with the alkaline treatment is of extreme importance in eliminating the toxins and protecting the kidneys against irritation and possible inflammation at the point of exit and probably preventing complications.

Nutrition.—The diet generally advised consists of gruels, broths, diluted milk, fermented milk, fruit juices, and fruit jellies. It is unadvisable to make milk the predominating article of the diet because of its tendency toward distention, and further, because so many patients tire of it so easily. The addition of cereals, fruit jellies, broths, and occasionally mashed vegetables, helps to keep the patient contented and furnishes at the same time an antiacidosis diet sufficiently rich in calories.

Elimination.—When the patient is first seen, usually within the first 24 hours of the onset, a cathartic is ordered. The kind of cathartic given depends on the acuteness of the onset and the presence or absence of gastrointestinal symptoms. I prefer calomel followed by a mild saline. Subsequently, the bowels are kept open by soap suds or bicarbonate enemeta. The bicarbonate irrigations, which are often used, also help in the elimination and in stimulating the kidneys. These rectal irrigations are carried out with a 2 to 5 per cent. sodium bicarbonate solution and about 1 to 2 gallons of this solution are used.

Counterirritation.—Whatever scientific principle may underlie the application of mustard to the chest, there is no other agent which will give as much relief to the aches and pains in the chest as does a good application of mustard paste. Where there are fine râles early or where there is an early tendency toward cyanosis, the mustard seems to have a very decided beneficial effect. In a disease where so little can be done once the graver pulmonary complications are well under way, the employment of any agency which promises something in the way of prevention of lung involvement, is desirable. The counterirritation is, therefore, looked upon as a desirable adjunct in the routine treatment of influenza. The mustard paste in the strength of about one of mustard to two of flour in the form of a paste, I like best. It can be applied to the entire chest and left for about 8 to 15 minutes, after which the skin is anointed with oil or vaseline. The application can be made every three or four hours or even more often if necessary.

Drugs.—The only drug that was used rather constantly is quinine, either as a tablet or in capsule

form. The alkaloid or any of its salts may be used. For an adult of average weight 0.3 gram every three hours or 1.5 to 2 grams in the first 24 hours, and about two-thirds this dose for each of the following three days is advised. The quinine seemed to have a decided effect on the fever, with a distinct and constant tendency to lower it. When perspiration is marked, and it usually is when quinine, large quantities of water, and alkalies are given, there is certainly a great loss of heat from the surface and a consequent lowering of the internal temperature. How valuable quinine is otherwise in influenza it is hard to estimate.

Other drugs, such as acetyl salicylic acid or pyramidon, especially when the headache and restlessness were marked, and not relieved by an ice cap, were occasionally given. The general impression gathered from observing the cases where drugs were used, is not favorable toward a continuation of drug treatment in influenza, with the possible exception of quinine. Our chief reliance, therefore, was on the complete rest, both during the active course and convalescence, large quantities of fluid, alkalies, and, perhaps, quinine and rectal irrigations.

Some of these measures mentioned here have impressed the author very favorably. They are reported not only because they are, in my opinion, of value, but I venture to make this outline with the hope of stimulating further trial and discussion. Only through fair criticism and open discussion may we hope to establish the treatment of influenza on a scientific basis.

1220 Grand Concourse.

INFLUENZA PNEUMONIA COMPLICATED BY EMPYEMA IN AN INFANT.

By A. LOBELL, M.D.,

NEW YORK.

THE report of the following case seems to me of interest for several reasons: (1) The age of the child and the uneventful recovery in spite of serious illness; (2) influenza pneumonia in the recent epidemics was invariably of the bronchial type, whereas this case presented the distinct lobar type; (3) the migratory character of the pneumonia; (4) the appearance of an unusual number of complications.

I. J., one year of age, a strong and healthy boy, weighing 23 lbs. There is nothing of interest in his previous history except that he had several attacks of acute tonsillitis, which were invariably followed by otitis media of a progressive nature.

In the latter part of December, 1919, he began with a rhinitis and tonsillitis, followed in the usual manner by a double otitis media. The fever, which was rather high, came down promptly after a double myringotomy. On January 8, 1920, about 38 hours after the incisions were made, the fever rose to 104°, pulse 140, respirations 46. The rise was sudden and the fever continued for six days, with marked remissions, so that during the twenty-four hours it was as high as 106° and as low as 99°. There was no regularity as to the time of these variations. Sometimes the highest point was in the forenoon and sometimes in the afternoon or evening. For a time it was hard to find definite signs of pneumonia, but on the fourth day there was a distinct consolidation of the right upper lobe. The fever came down by lysis, remaining stationary for about twenty-four hours. The ears were still discharging, but there was no evidence of any retention. He seemed to be comfortable and the breathing was satisfactory.

Nevertheless the fever jumped on January 16 to 105°, pulse 160, respiration 60, and behaved in a manner described above. On January 20 he was extremely restless, the right ear drum appeared congested, while the discharge was rather diminished. A myringotomy was performed, which gave him a restful night, but the fever remained high. One day later there was a consolidation of the greater part of the right lower lobe. The fever ceased again by lysis, staying normal for one whole day.

On January 23 the fever was up again and ranged as high as before, and several days later there was a definite consolidation of the left apex. On January 29 he had a severe chill, lasting 15 minutes. The next two days the respirations became more frequent and labored, the expression on the face more anxious, and he was visibly in some pain. The dullness over the right lung was rapidly changing to flatness, but we must emphasize that the vesicular murmur and the bronchial breathing were not in the least diminished, showing that one must never rely or expect such changes in the physical signs of the chest of infants when fluid superimposes on consolidation.

On February 1 the right chest was aspirated. A thin fluid was obtained, slightly turbid with a greenish tint, and on standing there appeared some fine flocculi. We did not wait for laboratory results, a simple intercostal incision was made and we obtained about 10 ounces of the same thin fluid described above. There were no fibrinous masses, such as are usually found, and the fluid drained very easily through a small sized tube.

Owing to the presence of a predominance of pneumonic processes over the comparatively mild empyema, the fever lingered for a long period. The drainage was perfect and the pleural cavity was closed within three weeks; the superficial wound also healed promptly. At no time was it necessary to probe the wound or facilitate drainage in any way.

In the latter part of February he had another attack of acute tonsillitis. In the early part of March he developed an ulcerative stomatitis and an acute general bronchitis. During the period of this illness he also suffered from difficult and very painful dentition.

To illustrate the virulence of the infection, it is necessary to state that 2 nurses and 7 members of the family were afflicted with the epidemic type of influenza immediately after the boy became sick.

Considering that the boy started primarily with a rhinitis and the irregular remittent fever, the migratory character of the pneumonia, the unusually thin fluid of empyema, with the absence of the fibrinous masses that are seen in empyema of the pneumoccus type, we may assume that the microorganism that played the most important rôle in this case was the influenza bacillus.

320 East 166th Street.

School for Nurses in Bohemia.—Prague is to have the first training school for nurses in Czecho-Slovakia. Realizing that the shortage of native doctors and nurses caused by the war was a very serious problem, and that the best way of solving it was to train native personnel, the new government, through Dr. Alice Masaryk, daughter of the president of the republic, appealed to the American Red Cross for assistance. A plan has been worked out, for which the Red Cross appropriated $20,000, and is already in operation. Two American Red Cross nurses, Miss Marian Parsons, former chief nurse of General Hospital No. 22, British Expeditionary Forces, and Miss Alotta Lentell, who served with the Red Cross in Flanders, have recently arrived in Prague to establish the school. Miss Parsons will be the superintendent and Miss Lentell will be her assistant. During the three years that these American nurses remain in Czecho-Slovakia, two young Czecho-Slovakian women will be sent to the United States to enter an American training school and prepare themselves to return to their own country and carry on the work initiated by the American nurses. The Massachusetts General Hospital, Boston, has agreed to accept these pupils as soon as they arrive in this country.

THE DIFFERENTIAL DIAGNOSIS OF LINGUAL ULCERS.

IT is important to make a differential diagnosis of ulcers consequent to dental defects and other ulcerative processes of the tongue. In the first place an ulcer due to carious teeth develops on the margin of the tongue and is usually a single lesion situated directly opposite a decayed tooth. Should there be several jagged teeth, several ulcers may be present. When due to a tooth the ulcer is very superficial, with sharply raised edges, a clean bleeding surface, and little if any induration at the base. If the lymphnodes are involved it is a purely inflammatory adenitis. Finally, the important symptom is the pain, which is invariably confined to the area of the ulcer; it is very sharp, giving the sensation of a raw surface irritated by a hard, sharp body each time the tongue is moved. As characteristic of these ulcers their rapid cicatrization after removal of the causative factor is to be noted; quite different is that of other lesions from which they must be differentiated.

A tuberculous ulcer may be seated anywhere on the tongue and is rarely single, there usually being at least three or four. It is superficial like a dental ulcer, but its margins are undermined, its bottom irregular and grayish; its base is not indurated but pain is severe. Involvement of the lymphnodes may be absent. The presence of yellow grains and the coexistence of thoracic or laryngeal lesions will indicate the nature of the process. A cold abscess of the tongue is crateriform, with thin undermined margins, while its fundus is filled with grumous pus; it does not bleed and is usually single without any tendency to cicatrization.

A syphilitic chancre is ordinarily situated on the anterior third of the dorsal aspect of the tongue, is single, very superficial, and more like an erosion of the mucosa. It has no margin and is oval in shape, with a smooth fundus and a distinctly indurated base. It is accompanied by an enormous, painless adenopathy involving numerous lymphnodes. Its evolution is rapid.

Mucous patches are common on the tongue, but can hardly be mistaken for ulcer. In the tertiary period ulcerated gummata may be encountered on the anterior third of the dorsal aspect of the organ. Usually there are three, or two at least. The ulcer is deep and as if punched out of the tissues. The bottom is as if glazed and covered by a yellowish coating, while the base is rather more infiltrated than indurated. Pain is trifling and the lymphnodes are not enlarged, and often an ulcerated gumma will be present with others which are not ulcerated.

Cancer of the tongue, at its phase of ulceration, is usually seated on the border and at the base of the organ. It is single, rather deep, with ragged, indurated margins. The bottom is granulating, reposing on a distinctly indurated base. There is early involvement of the regional lymphnodes. The pain is shooting, very sharp and intolerable, while salivation is profuse.

Actinomycosis, although rare, may occur in the tongue in the form of a mass seated in the midst of that organ, and containing the characteristic yellow bodies. Sporotrichosis is more frequent, at least in Europe, forming a dirty grayish-yellow tumor without falsa-membrane and with a marked tendency to extend. A lupous ulcer has ragged borders; the tongue is supple and indolent, and the lesions extend by gradual destruction of the tissues. Finally, it is always accompanied by lupus of the face or nose.

THE FUNCTIONS OF THE HOSPITAL.

IN the state of general mutation through which the medical profession, together with the rest of the world, is now passing, the hospital system is not exempt from criticism and probable change. The present hospital system, in many respects, stands condemned and a new system is in course of evolution. It is said that as the future of medicine is preventive, so the hospital of the future must be preventive as well as curative. That the functions of a hospital should be of a preventive nature is being recognized more and more. The Pasteur Institute in Paris and other similar institutions in London, New York and elsewhere, are managed in accord with these modern views. In order to obtain early and accurate diagnoses and to treat cases in the most thorough manner, the opportunities afforded by laboratory research are combined in the most felicitous way with hospital treatment. For this purpose the institutions above noted have hospitals associated with them in which the patients derive the benefit of the most special possible knowledge. When a special problem is being grappled with, hospital wards can be used with this sole object in view, while the sick person needing immediate help goes to the ordinary general hospital. The chief sign, however, which has been displayed as to the direction in which medical practice and hospital management are moving is the recently issued interim report of the Consultative Council of the British Ministry of Health. In this report is foreshadowed the development of a carefully thought out and ordered system founded upon principles which fundamentally differ from those which govern the usual medical and hospital practice of

the day. The basis of this system is prevention rather than the treatment of disease. The aim is to diagnose disease in its earliest stage and to prevent its development. For the successful conduct of this scheme, the services of the general practitioner are essential, as he alone has the opportunity of witnessing the inception of disease. Not only are the services of the general practitioner necessary, but he himself must be provided with the means for learning how to distinguish the beginnings of disease. Therefore, the British Consultative Council suggests that hospitals with adequate equipment for laboratory and clinical investigation should be supplied in all parts of the country for the behoof of general practitioners and patients. These hospitals will be largely of a preventive character. So that no means should be spared to arrive at a correct diagnosis, other hospitals will be at the service of the general practitioner to enable him, when an obscure case is met with, to avail himself of the knowledge of consultants and specialists. These hospitals will be large institutions staffed by experienced, trained, and skillful men and provided with every mode of diagnosis and treatment that human scientific knowledge and ingenuity can suggest. This at least is the ideal aimed at. This change in the character of the hospital will not come at once, nor is it desirable that it should so come. The course of development will be slow and ruled by well considered judgment. The various functions of the hospitals —treatment, teaching, research, discovery, and prevention—are all necessary, and the main object of those interested must be to find out how each one of these functions can be best performed without injuring or prejudicing the others. The scheme suggested by the British Consultative Council, although in certain respects seemingly impracticable, at any rate points to a new conception of the functions of the hospital.

ABSCESS OF THE LARYNX IN CHILDREN.

LARYNGEAL abscess is relatively uncommon in early life and is the consequence of infectious diseases, such as measles, influenza, scarlet fever, diphtheria, and typhoid, and lastly, variola. The process is very exceptional in the latter affection, as well as in scarlet fever, and is more prone to occur in diphtheria, measles, influenza, and as a complication of ordinary laryngitis. In cases of retropharyngeal abscess the pus may burrow on each side of the larynx and afterward form a purulent collection in front of the larynx and trachea as well. During typhoid fever an abscess of the larynx may develop, forming a morbid entity known by the French school under the name of laryngotyphoid. In measles the laryngeal suppurative process may be a primary one, or may appear as a secondary complication, as it does in the laryngitis of measles, be it diphtheritic or not. During the evolution of diphtheria or convalescence from this infection. cases of endolaryngeal abscess have been known to occur before intubation had been done, but no cases of perilaryngeal abscess have, so far as known, been reported. It is to be remarked that intubation appears to predispose the parts to the occurrence of this complication. Laryngeal abscess in children also arises as a consequence of ulcerative processes in the larynx; however, they never contain the bacillus of diphtheria, and appear to be related to perilaryngeal lymphangitis and adenitis. The site of these abscesses varies quite considerably. At times they are endolaryngeal or submucous, projecting into the laryngo-tracheal lumen, at others, perilaryngeal in location, in which case they may be prelaryngeal, on the sides of the larynx, or even retrolaryngeal. All these processes have an obscure symptomatology in children.

From the clinical standpoint, two quite distinct conditions are met with in practice. In the first of these the abscess is evident; there are, so to speak, no clinical symptoms, but rather physical signs, such as tumefaction and edema of the neck. In the second, the abscess is latent, giving rise to no clinical symptoms or objective signs. In most instances the onset of the abscess formation takes place from the tenth to the fifteenth day of the process giving rise to it, but whether the abscess is latent or not, it undergoes its evolution rather insidiously, without giving rise to any marked general symptoms. The prognosis should always be guarded because of the possibility of sudden death. To make the diagnosis, especially when the abscess is clinically latent, it will, in the majority of cases, be enough if we will merely remember that such a complication can arise. Hence, the necessity of examining the larynx and the intubated region much more frequently than is generally done at present. When the diagnosis has been made the abscess should be freely opened without delay, as by this means sudden death of the little patient is avoided.

THE MAN AND THE HOUR.

OPPORTUNITY, George Eliot said, is but an unfecundated egg to the man who can't use it; but what it is to the man who can and will was strikingly demonstrated in the life work of Gen. William C. Gorgas. In 1899 he was an army surgeon, 45 years old, who had by faithful work and seniority attained a majority. Having had the good fortune to contract and recover from an attack of yellow fever early in his army life, he was sent as an immune to Havana with the Army of Occupation. There he, in common with other army surgeons and Colonel, now General Wood, was pestered by Dr. Finlay to try out the latter's theory of the mosquito transmission of yellow fever. Sceptical, if not scornful, at first, the army authorities were annoyed by Finlay's persistence; but finally, like the woman who is said to marry a man to get rid of him, they yielded and appointed the Walter Reed Commission to test the matter. Major Reed's capital work having demonstrated conclusively the agency of the mosquito in the propagation of yellow fever, it devolved upon Major Gorgas, as sanitary officer of the city, to put the new knowledge to practical use. How he responded to opportunity's call and how this response

brought out his latent abilities and sharpened his reasoning faculties, and the brilliant results which he achieved then and there and later at Panama and on the West Coast of South America, are facts of history known to the whole world. Opportunity knocked and Gorgas opened wide the door, winning for himself undying fame and the gratitude of a regenerated tropical world.

Anaphrodisia from Mercury.

At the winter session of the Sociedad Española de Dermatologia y Sifiligrafia (*La Medicina Ibera*, March 13, x, 125) two papers were devoted to this subject. Azuá mentions several personal cases in which an intensive mercurial cure for past syphilis as preliminary to marriage was followed by genital debility characterized by imperfect erections and the general picture of sexual neurasthenia. Suppression of the mercury was followed by complete recovery. Casal followed with an account of similar personal experience and reported the case of a man aged 25, with syphilis of one year duration, who received twenty injections of mercury benzoate, at the end of which he complained of anesthesia and impotence. The condition was found to be radicular, obtaining in the entire distribution of the third sacral root, and was regarded as a toxic radiculitis due to mercury. The patient confessed to being an onanist. The condition disappeared after cessation of the mercury treatment. It is possible that these cases would not have occurred in non-syphilitics and that syphilis may have been the first agency to affect the nerve substance, but a study of several cases shows that the picture does not appear until after a number of injections have been made. This fact and the other that improvement occurs only on stopping the remedy are sufficient to implicate the latter. Castelo, Sainz de Aja, and other who have had a very large experience in injecting mercury for syphilis have never witnessed this phenomenon.

The Psychic Factor in Anesthesia—Death in Status Thymicus.

Since sudden death from trivial causes occurs equally in subjects with and without enlarged thymus, some third factor must be invoked to explain the primary syncope which precipitates the fatal issue. It is possible that this is a neuropsychic excitability resulting in predisposed subjects from the suggestion of the approaching operation or the narcosis which is to precede it. This mental state may or may not be akin to that which is seen in Graves's disease before operation. At a recent session of the Anatomical Society of Paris (*Bulletins et mémoires de la Société anatomique de Paris*, January 20, xvii, 1), Bretignier reports a case of operation on a patient with salpingitis, aged 25, and with sound heart and lungs. She had begun to inhale chloroform and at the expiration of 6 minutes, after having inhaled 6 or 7 gms., there was sudden arrest of the heart's action. Despite all attempts at resuscitation the swoon proved fatal. Autopsy showed absence of any compression of the trachea but the thymus weighed 30 gms. just after removal. Its dimensions were 11 cm. by 7 cm. The author mentions similar cases, including two others by Lapointe, who was the operator in the present case, in which the weight of the organ exceeded 20 gms. All three of these patients had shown marked nervousness and anxiety at the beginning of anesthetization.

News of the Week.

Provision for Blinded Soldiers of the Allies.—The board of directors of the Permanent Blind War Relief Fund for Soldiers and Sailors of the Allies recently allotted 10,000 francs a month for the remainder of the fiscal year, or a total of 100,000 francs, for the maintenance of the Reeducational School for the Blinded Soldiers of Serbia, at Belgrade, a like amount was allotted for the Reeducational School and Workshop at Bucharest, Roumania, and 200,000 lire for the Comitato Torentino per l'Assitanza di Ciechi di Guerra, of Italy, making a sum equivalent to $80,000. According to William Nelson Cromwell, chairman of the executive committee, the organization has 18,000 members.

"The Child Welfare Special."—The Children's Bureau of the United States Department of Labor recently issued a pamphlet on "The Child Welfare Special," which is a motorized child welfare station. This was put into the field last summer for the purpose of informing mothers of children in rural districts concerning all the things that mothers of city children may learn at child health centers. The Special has visited five rural counties, none of which contained more than one town of over 2,500 inhabitants. Four of these were agricultural counties and one was in a mining section.

Typhus Scare Delays Ships at Quarantine.—The White Star liner *Olympic*, with 2,221 passengers on board, and the *Dante Alighieri* of the Trans-Atlantica Italiana Line, with 1,198 passengers, were held in Quarantine for nearly two days recently because of the presence among steerage passengers of the former of 180 Serbians and inhabitants of other typhus-infected areas of Europe, and because the latter had not carried out the rules and regulations of the United States Public Health Service in relation to passengers embarking at foreign ports. No cases were found.

Bonus Opposed by Physicians.—Caduceus Post No. 818, of the American Legion, has declared its unanimous disapproval of the bonus for ex-service men. The officers of Caduceus Post are: *President*, Dr. Howard Fox; *Vice-President*, Dr. Harlow Brooks; *Second Vice-President*, Dr. George E. Maurer; *Third Vice-President*, Dr. G.M. Hammond; *Secretary*, Dr. Samuel Bradbury, and *Treasurer*, Dr. William F. Cunningham.

Shortage of Doctors in the South.—The sum of $12,000 has been subscribed to an emergency fund to make possible the admission of the large number of applicants to next session's freshman class of the University of Virginia at Charlottesville. In view of the acute shortage of physicians in the South and of the necessity of turning away desirable applicants, a campaign was inaugurated by the medical faculty of the university to raise $16,000. A nucleus of $2,400 was given by the members of the medical faculty. The first-year medical class added to this an unsolicited donation

of $1,000, and the citizens of the vicinity contributed $5,825.

New York Association for Medical Education.—At a meeting of the Directors of this association, June 21, 1920, the work of the past year was reviewed approvingly and the following officers were elected to carry out plans devised for the ensuing year: *President,* Dr. Haven Emerson; *First Vice-President,* Dr. George David Stewart; *Second Vice-President,* Dr. Glentworth R. Butler; *Secretary,* Dr. Otto V. Huffman; *Treasurer,* Dr. Arthur F. Chace. A special vote of thanks was extended to Dr. Wendell C. Phillips, the retiring president, for his valuable services as the founder and organizer of the association.

Nurses Honored.—The Florence Nightingale Medal, the highest honor at which nurses aim, was recently bestowed by the International Committee of the Red Cross at Geneva upon five American nurses who "especially distinguished themselves by great and exceptional devotion to the sick and wounded in peace or war." The nurses so honored are: Helen Scott Hay of Washington, D. C., chief nurse of the American Red Cross commission for Europe, who began her war service in 1914; Florence Merriam Johnson of New York City, director of the Department of Nursing of the Atlantic Division, American Red Cross; Martha M. Russell of Boulder, Col., who went to France in July, 1917, to organize American Red Cross nursing activities in the war zone; Lydia K. Meirs of Boston, who went to Europe for the American Red Cross, but was transferred to the Army Nurse Corps, in which she performed notable service under fire at the front; Alma E. Forrester of Chicago, who sailed for service in Russia on the relief ship Red Cross, in 1914, and was in Europe throughout the hostilities. Mary E. Gladwin of New York City, who sailed on the relief ship Red Cross, in 1914, for service in Serbia, where she remained five years.

Brig.-Gen. Robert E. Noble, M.C., U.S.A., who was with Gen. Gorgas during his last illness in London, will head the mission to the West Coast of Africa which had been planned by Gen. Gorgas at the request of the British Government.

One Hundredth Anniversary of Bowdoin Medical School.—The centenary of the establishment of Bowdoin Medical School, Brunswick, Me., was observed by exercises held in the First Parish Congregational Church, June 23.

Physicians Want Penal Law Amended.—Four hundred doctors of New York City have signed a petition, which was recently presented to the Judge presiding in the Bronx County Court, at the time of the conviction of a physician of the Bronx for manslaughter in connection with a so-called "unnecessary operation," and which is said to be a forerunner of a movement among members of the medical profession of New York State to amend the penal law so as to make it possible for physicians to perform curettage as a life-saving measure without the fear that the operation may lead to a charge and possible conviction of manslaughter.

Charitable Bequests.—Under the terms of the will of Mrs. Anna M. Schmitt-Raier, who died in New York City last December, the German Hospital of this city will receive $69,866.

Obituary Notes.—Dr. John Horner died at his home in White Water, Kansas, June 20, in his eighty-seventh year. He was graduated from the Eclectic Medical College, Cincinnati, in 1880.

Dr. CHARLES D. MCCARTHY, formerly mayor of Malden, Mass., died of apoplexy in his home in that city June 22 at the age of sixty. He was graduated from New York University Medical College in 1882. He served as a member of the Malden Board of Health from 1886 to 1907, when he resigned to accept the office of mayor. He was a member of the staff of the Malden Hospital, and was a fellow of the Malden Medical Society.

Dr. JOHN CALVIN FULTON, a Civil War veteran, and practising physician for fifty years, died at his home at Bluffton, Ind., June 22, at the age of seventy-five.

Dr. JAMES C. BARKER of New Milford, Conn., died of apoplexy recently at the age of sixty-eight. He was graduated from Yale University School of Medicine in 1879. He served as local health officer for twenty-five years.

Obituary.

WILLIAM C. GORGAS, M.D.,

MAJOR-GENERAL, M. C., U. S. ARMY.

MAJOR-GENERAL WILLIAM C. GORGAS, distinguished sanitarian, and former Surgeon-General of the United States Army, died in London, July 4, at the age of sixty-six. He had been seriously ill for three weeks, following a stroke of paralysis. Bright's disease was the immediate cause of death.

General Gorgas was born in Mobile, Ala. He received his preliminary education at the University of the South, Sewanee, Tenn., and was graduated from Bellevue Hospital Medical College in 1879. He applied at once for a commission in the Medical Corps, U. S. Army, and was made First Lieutenant, and was sent to Fort Brown, Texas. While at this post he contracted yellow fever, the immunity thus acquired being of great service to him in his work of abolishing this disease which forms one of the most interesting and important chapters in the history of preventive medicine and sanitation.

The first great opportunity presented itself during the Spanish-American War, when Gorgas was placed in charge of the yellow fever wards of Las Animas Hospital in Havana. His prompt utilization of the confirmation by Reed and his associates of Finlay's theory regarding the mosquito as the means of the transmission of yellow fever enabled him to inaugurate the well-known sanitary campaign which resulted in the ridding of the Cuban capital of this plague. When it became necessary, in 1905, to render sanitary the Isthmus of Panama in order to make possible the completion of the Canal, Gorgas was assigned to the task. The achievements which followed in his campaign of extermination of malaria and yellow fever warranted his well-known prophecy "that some day a case of yellow fever will be regarded as a medical curiosity."

In 1913, at the request of the British Government, Gorgas went to South Africa to investigate conditions in the Rand mines, where the natives were dying from epidemics of pneumonia. The carrying out of the measures which he recom-

mended as a result of his investigation resulted in practically putting an end to the epidemics.

In 1914 he was made Major-General, and the following year he became permanent Director of the International Health Board of the Rockefeller Foundation. In October of last year he returned from a successful campaign against yellow fever in Guayaquil, Ecuador, undertaken at the request of the Foundation. At the time of the illness which ended his career he was en route to the West Coast of Africa to study sanitary conditions in that region.

During the world war, Major-General Gorgas, as Surgeon-General of the Army and head of the Medical Department, inaugurated the stupendous undertaking of the caring for our soldiers at home and overseas, the full significance of which cannot be appreciated until its history is written.

General Gorgas was a member of many medical societies, and had had many honors conferred upon him, among them the gold medal of the American Museum of Safety, the Mary Kingsley Medal from the Liverpool School of Tropical Medicine, and the insignia of Knight Commander of the Order of St. Michael and St. George, conferred recently by King George.

Correspondence.

DECEPTION AND SELF-DECEPTION, IN THE PRACTICE OF MEDICINE.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—I am coming up against both these unfortunate conditions frequently. It is very hard both for patient and doctor, I mean especially, the general medical adviser of the patient. If the physician wishes the best interest of his patient, as he does and should, he seeks the best medical or surgical advice, if he is at fault, or even when he believes he knows and that a consultant's judgment will confirm his own. When this has proved to be true, the wise doctor does not consider it often wisdom to consult in behalf of his patient a third physician, who has special knowledge in the direction of that disease which has been determined to exist by the two previous physicians. Still he is apt to yield to an expressed wish on the part of the patient and it is done. Sometimes, there is practically accord between the three physicians; sometimes, the specialist differs from the others. Then we must have a fourth physician, also a specialist, meet the others in consultation, and after hearing their opinions, he either agrees or disagrees. If he agrees, well and good; if he disagrees, a fifth physician must be called in, and here again there may be equal division of judgment, or it may be three against one. In the former case, matters are settled, at least, for a while; in the latter case, one is again unsettled, or else, perhaps, the patient abides by the opinion given originally by his own physician.

Such a condition of affairs, as I have briefly portrayed, is to-day not infrequently encountered. The net result is sooner or later to have a neurasthenic patient who believes no one and is bandied around from one specialist to another. Finally, the good, square, all-around physician becomes weary of well doing and soon wishes to throw up the case or does so. Meanwhile, has he received proper pecuniary return for what in reality are very valuable services? As a rule, no. The consultants, general or special, get their remuneration; he does not. Gratitude is much talked of and probably given for a while. Ultimately he is regarded as unsympathetic or almost cruel, and in place of a firm and loyal patient and friend, he has neither.

I have related the foregoing from actual experience, repeated several times in a decade or less, and by its narration I wish to illustrate what I mean by deception and self-deception in the practice of medicine. The doctor may be of the sort who feels obliged, by what to him are major considerations at the time, to go on almost without time limit, pandering as it were to what he knows is purely an effect on the neurones, such as we find in neurasthenia and hysteria, and in so far as he does so, after awhile he deceives his patient. The patient is self-deceived by his disease and it is often problematical how he or she will become undeceived. In my judgment, he is sometimes never undeceived; fortunately, in other instances, the patient finally and as a last resort reaches the conclusion that his own original physician, faithful, true, conscientious, and unrewarded, is in reality correct. Why should clever, hard-working, conscientious men embark and continue in the general practice of medicine at the present time? Cui bono? I cannot answer; perhaps the editor, or maybe someone who reads these lines, can and will.

BEVERLEY ROBINSON, M.D.

NEW YORK.

MEDICAL MEN IN THE HALL OF FAME.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—The fully justified suggestion of my friend, Dr. S. A. Knopf, that American physicians be represented in the Hall of Fame having caused the mention of my name among the nominees, I beg to submit to your readers, through your kindness, the following letter written by myself to the Senate of the New York University relative thereto:

Though greatly honored by the fact that I have been nominated for the Hall of Fame, I deem it my duty to state that the kindly advocates of my labors who suggested the nomination must have been unaware of the fact that a living man is ineligible. An editorial writer suggested that the candidate meant was a laryngologist bearing my name and not the endocrinologist now living. But here again some oversight has caused a misinterpretation of facts, for I happen to be that laryngologist, who took up endocrinology nearly thirty years ago as a normal offshoot of the laryngological field.

I do hope, however, that American Medicine will ultimately get its due if I succeed in proving, as many believe I am doing, my contention of many years' standing, that the ductless glands can so transform internal medicine and therapeutics as to place these branches on the footing of a science, and that it is only through amplified knowledge of these organs, to which so many able men are now contributing, that several of the great destroyers of humanity now resisting all efforts can be conquered. If any credit is to accrue to me on that score, the good actually done and the appreciation of my colleagues will amply reward my efforts, and ultimately perhaps merit your kindly interest.

CHARLES E. DE M. SAJOUS.

2043 WALNUT STREET.
PHILADELPHIA.

OUR LONDON LETTER.

(From Our Own Correspondent.)

LONDON, June 11, 1920.

First Annual meeting of the Society for the Prevention of Venereal Disease.—The first annual meeting of the Society for the Prevention of Venereal Disease was held at the Barnes Hall, Royal Society of Medicine, 1 Wimpole street, London, on Thursday evening, June 3, 1920, the President, Lord Willoughby de Broke, occupying the chair. Lord de Broke's able and lengthy speech was concerned for the most part in recapitulating the aims and objects of the society and particularly in defending it from the charge that in advising immediate self-disinfection it tends to promote immorality. Also he asserted that the policy of the government as represented by the National Council for the Prevention of Venereal Disease, was inconsistent and half-hearted and in his opinion, the only wise, the only human, the only statesmanlike course, is to recognize the fact, that all the preaching, lecturing and incitement to lead a healthy life, have at present failed to suppress the sexual instinct to such a degree as to have any effect on the incidence of venereal disease, and that therefore, if the disease is to be attacked successfully, it must be attacked at a place which is so well called by Colonel Harrison, the weakest link in the chain, and the weakest link in the chain of infection is immediately after connection has taken place. Hence, the whole aim and object of this society is to urge the Government, to bring pressure upon the Government, to bring pressure upon all public bodies to issue such instructions to men and women of this country that will enable them to take advantage of the latest teachings of science in order that they may themselves use immediately after connection, if connection there must be, such simple disinfectants as have been proved to be efficacious in destroying immediately the spirochete and the germ of gonorrhea. With reference to the moral aspect of the question the speaker declared that the above is not only the common-sense point of view, but it is the moral point of view. In the opinion, the highest moral attitude that the State can adopt is the safeguarding of the health of the country, and the members of the society utterly decline to join any school of thought which is going to suppress knowledge from British men and women, and will not be responsible to future generations for having suppressed knowledge, which, if it is properly and intelligently and scientifically applied, may very well prevent thousands of them from hideous sufferings in the future and may also cause thousands of healthy children to be born, who otherwise would never have seen the light of day. It was pointed out that twelve towns have already given instructions that the inhabitants shall be given the opportunity of being taught the advantages of immediate self-disinfection and being made acquainted with the technic of the same, and Portsmouth has led the way.

The main object of the meeting was to move a resolution whereby a certain obstacle in the way of the adoption of this means of prevention may be removed, the removal of which will make immediate self-disinfection accessible to the general public. The obstacle referred to is contained in a clause in an act termed the Venereal Disease Act of 1917. The gist of this clause is as follows: That on and after Nov. 1, 1917, a person shall not hold out or recommend to the public by any notice or advertisement anything for the prevention, cure or relief of any venereal disease. This clause was inserted with the view of preventing unqualified persons, such as druggists, from treating venereal diseases or from selling so-called cures. The resolution reads thus:

"That inasmuch as the Ministry of Health has failed, and public bodies, including the London County Council, have declined to provide the means for delayed disinfection against venereal disease at Ablution Centers, this meeting calls upon the Ministry of Health and upon local authorities to instruct all qualified chemists to sell such means of immediate self-disinfection against venereal disease as may be approved from time to time by the Ministry of Health or by medical officers of health. Dr. Saleeby seconded the resolution and Sir James Crichton Browne supported it in the usual eloquent manner. In his speech Dr. Saleeby pointed out that the National Birth Rate Commission, in its report issued recently, hold that no difficulty of an official kind should be placed in the way of obtaining disinfectants by individuals for use after exposure. The Commission further tenders the advice that any difficulties of any administrative kind which may now prevent registered chemists from selling such disinfectants should be removed, provided such preparations are only to be sold when accompanied by a notice that they are to be used for disinfection only and are useless for treatment. Sir Frederick Mott, who also supported the resolution, emphasized the fact that the disabilities produced by syphilis are colossal and said that he was perfectly certain from an economic point of view that it would be of the greatest value to the Government to do everything in its power to support the propaganda of this Society both from a health point of view and from an economic point of view. The resolution was carried unanimously. Sir William Arbuthnot Lane, the treasurer, did not read the report; it was taken as read. However, Sir Arbuthnot made some apt remarks on the subject of the Society's finances. He drew attention to the fact that this is one of the most wonderful societies that ever existed; it ought to be called the Suicide Club. Men had been got together who make their living out of this disease, men whose interest it is that this disease should continue to be rampant. The Society is almost entirely supported by funds obtained from these men. He thought it the most altruistic and philanthropic institution that has ever been made in the history of the world, and he deemed it a pity that the Society should have to depend on these friends from whom the Society has to beg to provide subscriptions for this institute. The Society and its policy are not in the interest of the medical profession, but in the interest of the public, and he thought that the members of the Society ought to do their best to obtain from those who are to gain most from the prevention of venereal disease,

what indeed the medical profession is going to lose. Perhaps, on the whole, the most interesting part of the proceedings was the reading of the Secretary's report by the Secretary, Mr. Wansy Bayly, and this for more than one reason. Mr. Bayly was the prime mover in the evolution and development of the Society, and is working for its success as hard as ever he was. His report gives a lucid and succinct account of why the Society was formed and the ups and downs met with in the course of its formation. The reason for its formation was the publication in August, 1919, of the report of Lord Astor's Interdepartmental Committee of which a description was given in my London Letter a few weeks after the issue of the report. Mr. Bayly, after reading this report, resolved to endeavor to organize a new Society in order to lay before the public the purely scientific aspect of the prevention of venereal disease by immediate self-disinfection. At first in London when he mooted the idea of forming such a Society the two gentlemen he approached, because he was aware they had expressed themselves in favor of prophylaxis, gave most damping replies. In Edinburgh and Glasgow the majority of medical opinion was favorable to such a scheme, and on September 22, 1919, the first meeting of the Venereal Committee took place at Mr. Bayly's house in London. A month later the committee formed itself into the Society for the Prevention of Venereal Disease and a provisional constitution drawn up by Mr. Bayly was accepted without amendment. On December 10, 1919, Lord Willoughby de Broke, the president, raised the question, in the House of Lords, of immediate self-disinfection as a prevention of venereal disease and asked for papers relative to incidence of venereal disease in Portsmouth Military Area. The Ministry of Health replied in a white paper in February last, in which inaccuracy in former statements was admitted. The Society is now an undoubted success and established, as Mr. Bayly states, on foundations built partly on the solid rock of the sympathy of the thinking public and partly on the somewhat shifting sands of financial support by voluntary subscriptions.

British National Council for Combating Venereal Disease.—On Monday evening, June 7, last the British National Council for Combating Venereal Disease held its annual meeting. Lord Astor, who presided, said in part that before compulsory treatment of venereal disease could be even talked of, it must be seen to that there were enough facilities for diagnosis and treatment for those affected, and at present this provision was inadequate. Nor must it be forgotten that compulsion would inevitably lead to much concealment and a consequent failure to apply for treatment. Half the people who talked of compulsion had not realized the special difficulties or studied previous failures. During the war the disease was reduced more by women police and drink control than by all the regulations. Any one who had made a study of the social scourge knew how Abraham Flexner exposed the so-called success achieved on the European Continent through the system of inspected houses. Foreign countries had neither wiped it out nor produced peoples cleaner in body and mind, and it must not be forgotten, either, the lack of success of the Contagious Diseases Act in England. Some people talked as if they had succeeded; they had not. The disease increased in the army during their operation and decreased when they were abolished. Speaking as to policy, Lord Astor said they wanted to stimulate medical education. It was essential to bring the general practitioners more into touch with modern science. They proposed to work through the medical schools and the clinics, of which latter there were now 172. This was not enough; more and often better ones were needed. Greater facilities for diagnosis were wanted, with special reference to the needs of pregnant women, and seamen, and also hostels for girls. It was necessary to continue and increase propaganda both for adults and adolescents. But while improving organizations at home, foreign countries must not be forgotten, the propinquity of nations, the extent of modern traveling, the seafaring population, and their special temptations. He hoped the League of Nations, through its health section, would help to solve this and other world problems.

British Hospital in Paris.—A meeting was held on June 7, 1920, at the British Chamber of Commerce in Paris, Lord Derby being in the chair, to consider the best means to raise funds to help the Hertford British Hospital in Paris. The hospital was founded and endowed in 1871 by Sir Richard Wallace, but to-day the endowment is insufficient for its needs. The management is now in the hands of a committee appointed by the Foreign Office. It is considered that it would be a great pity should the hospital be compelled to close or even to restrict its work, as it has been invaluable to British subjects in the French capital.

Memorial to Sir Victor Horsley.—The following letter over the signature of Sir W. Arbuthnot Lane, Dr. Edward J. Domville, and Sir John Y. W. MacAlister appeared in the London lay press of June 5, 1920: "It has been decided at a meeting of friends and former colleagues of the late Victor Horsley to take steps to commemorate his services to science and the Empire by the foundation of a lectureship bearing his name. The tragic circumstances of his untimely death in Mesopotamia are still fresh in remembrance, and though the absence of so many medical men on war service prevented an earlier movement, we are satisfied that it is not too late for the recognition in a permanent form of Sir Victor's life and work. He was one of the most noteworthy students of University College Hospital, a very distinguished medallist and graduate of the University of London, and a leader and the first chairman of the representative meeting of the British Medical Association. He was a pioneer in the research work connected with the surgery of the brain and nervous system, the causation and treatment of myoedema, and as secretary of the Commission to inquire into the value of Pasteur's method of treating rabies, his investigations at the Brown Institute were of the utmost value in stamping out rabies in Great Britain. Outside his strictly

professional work there was scarcely any subject affecting the moral and physical welfare of the nation in which he was not actively interested. As a strenuous fighter, firm in the belief of the truth of his own convictions, he was, it must be confessed, often in conflict even with his best friends and colleagues, and sometimes he took action which alienated them from him, but nevertheless we find that very many of those offended are anxious that misunderstanding and invective should be forgotten, and that the sterling qualities of the whole-hearted student and unselfish worker should be recognized by a perpetual memorial. The exact form in which the lectureship should be constituted or the corporation to which it should be entrusted is left for the consideration and decision of the larger committee which is in course of formation. It is, however, suggested that the most appropriate trustee would be the Senate of the University of London, and that the subject of the lecture should be left widely open so as to secure the services of men distinguished in some department of public life who might consider it an honor to be the 'Victor Horsley Lecturer' for the year. As it is desired that the memorial should be as widely representative as possible, the maximum subscription is limited to a guinea ($5 or thereabouts). All letters and subscriptions should be addressed to Dr. Edward T. Domville, Symondsbury, Bridport, Dorset."

I have quoted the letter in full because it expresses well the very high place in medical science occupied by Victor Horsley and the estimation in which he is held by his professional brethren. Another reason is that his fame is international; he has always been very highly considered in the United States, and some of his American admirers may wish to contribute to a memorial of a really great scientific man.

Obituary.—Dr. George Ernest Morrison, aged fifty-eight, died at Sidmouth on May 30 last. Dr. Morrison graduated in medicine from Edinburgh University in 1882. He was an Australian of Scottish ancestry, and received his early medical training at Melbourne University. But his tastes did not lie in the practice of medicine. He was afflicted or blessed with the "wanderlust" and had an absolute passion for travelling. He walked thousands of miles outside the beaten track and explored parts of the world of which little was known. He happened to be in China during the Boxer outbreak, in which he took part as a combatant officer, being severely wounded. But Morrison's fame will rest, for he was one of the famous men of the world, on his work in China. He was *Times* correspondent in China for some time and gained a wide experience of Chinese affairs. This knowledge combined with a strong personality gained for him the confidence of the Chinese Government, by which he was appointed political advisor to the Government. Morrison wielded almost supreme power in China, as his advice was invariably sought and almost invariably taken, especially as regards foreign politics.

Many medical men in the United States and Canada will learn with regret of the death in London after a short illness of Doctor John Hamilton Fullarton. Dr. Fullarton was born in 1856 at Brodick in the Isle of Arran. He was of the family of Fullartons of White Farland and Kilmichel, which they have held since the time of King Robert the Bruce. The progenitor of the family is mentioned in Sir Walter Scott's "Lord of the Isles" as Fitz Louis. On entering the University of Glasgow he had a most distinguished course and there and at Leipzig, where he went later, he won bursaries to the value of £1,500. For some time he was a lecturer at Glasgow University. Many scientific distinctions were conferred upon him. In recent years Dr. Fullarton practised as a consultant, but it was his intention shortly to give up his active work.

2. Bodily Mechanics and Medicine.—Lloyd T. Brown chooses the term bodily mechanics instead of faulty posture because faulty posture is only one of the results which may occur when the human body, considered from a mechanical point of view, begins to get out of line. It may be and often is one of the first symptoms to occur and may be present without any immediate effects in much the same way that carious teeth and adenoids and constipation and many another condition may exist for an indefinite time without any ill effects. Differences of opinion as to what constitutes good mechanics of the body have retarded the development of the subject. How may one know what is good and what is bad mechanics? In order to get some definite data to work on, it seemed wise to examine a sufficient number of so-called normal men to give one a point of view. The opportunity was given the writer in 1916 to examine all the men of the freshman class at Harvard. The examination consisted of taking a tracing of every man as he stood in a natural standing position. When these tracings were collected and studied it was found that they fell into four groups, representing good and fairly good bodily mechanics, bad and very bad bodily mechanics. There were 746 men examined, of whom 7.5 per cent. were in the good group, 12.5 per cent. in the fairly good group, 55 per cent. in the bad group, and 25 per cent. in the very bad group. In other words, 20 per cent. of the men used their bodies in good or fairly good mechanical lines, and 80 per cent. were bad or very bad. In order to find out if there was a possible relation between this classification and the physical findings and symptoms, the statistics were studied in relation to the medical findings. This study showed that no man in the first two groups complained of backache, while over 6 per cent. of the third and over 8 per cent. of the fourth gave a history of backache. Functional albuminuria was much more common in the third and fourth groups than in the first two, and more common in the fourth than in the third. Operations for appendicitis were progressively more common as one went from the first to the fourth group. On the other hand, the removal of the tonsils and adenoids, which was done as a rule in early life, occurred rather more frequently in the first two groups. In the fall of 1919 a similar examination was undertaken. This time, however, the bodily mechanics was computed by two criteria; first, how the individual used his body in standing, judging not only from the position which he assumed naturally, but also from the position he assumed upon being directed to put forth his best efforts; and, second, how the individual used his feet. The classification of this group of 513 freshmen placed

.97 per cent. in the good group, 14.8 per cent. in the fairly good group, 49.3 per cent. in the bad group, and 34.8 per cent. in the very bad group. A comparison of this classification with the mechanical findings showed that in the fourth or very bad group, graded so on account of the feet, slightly over half had a history of trouble either in the past or at the present. Usually, however, the compensation was fair for ordinary activity. Like the 1916 experience, in the first and second groups the men did not give histories of backaches, but there was a definite percentage among the third and fourth groups, being nearly 10 per cent. in the fourth, which was higher than in the third. Functional disturbances, such as tachycardia, instability of the systolic blood pressure, etc., were most common in the students of the fourth group. Also the frequency of constipation, headache, etc., was greater in the fourth than in any other group. Forty cases of albuminuria, or 7.7 per cent., were found. The relation between such faulty mechanical use of the body as seen in the fourth group and the findings given is of course very obscure at the present time, and until some scientific experimental work, which takes into account the possible effects of good and bad mechanical use of the body on the physiology of the body, is done, it will remain in doubt. The point that the cases cited as having been treated by the writer brings out is not that the correction of the mechanical defects is the whole thing, but that the correction of them is one of the ways to help nature compensate for the defects which may be present from heredity, environment and occupation.

6. The Problem of the Malingerer.—Judson C. Fisher discusses the subject of malingering from the industrial point of view, and considers it a real problem, recognized by every industrial surgeon. He classes malingerers as real malingerers and exaggerators. A real malingerer, he holds, is a real crook and should be condemned as such. The real malingerers are about one in a hundred, in his experience, among all classes, and thirty per cent. among Italian and Polish longshoremen. The exaggerators are those who have a legitimate accident. After deriving benefits for a legitimate period for their types of accidents they malinger and prolong disability so as to get all they can. This class consists of about twenty-five per cent. of all accidents and seventy per cent. of longshore cases. The age of malingerers is dependent upon local conditions. The amount of money coming into the family from other members, lodges, sickness, insurance, etc., plus perhaps rents or dividends from building and loan associations, often determine the length of disability at all ages. In general, however, more malingerers are found from thirty-five to sixty-five than among the younger ages. Mentally he classes malingerers as abnormal—they are out of touch, as it were. Revenge, ambition for sympathy and alms, mimicism, fanaticism or manic depressive psychosis, combined with cunning, is the final diagnosis in nearly every case. To detect the malingerer is to be of service to both employer and the rank and file. Detection is a matter of study. Complaints of subjective symptoms only make a good case for the neurologist, and every industrial surgeon should have neurological training. The detection of malingerers calls for the cooperation of the able industrial surgeon, the employer, the honest employees, the industrial accident boards, and society as a whole.

7. Group Study in the Surgery of the Head.—Seymour Oppenheimer holds that to those who read the signs of the times it must be evident that the practice of medicine is in a state of transition—that it is being slowly but surely revolutionized—that the individualistic is being superseded by the combined or group method of practice. This applies to the surgery of the head and neck no less than to other branches. It is only by means of laboratory tests, close clinical observation and correlation of findings by the component members of the group, and aided further by careful studies of the body metabolism, that one may hope to elucidate the complex and often all too obscure symptomatology of head and neck lesions, and if it is admitted that the individual physician cannot specialize in all branches of medicine and surgery.

6. Infrequency of Intestinal Parasites in Young Children.—Stafford McLean undertook this study for the purpose of determining the frequency of helmenthiasis in children attending an out-patient department in New York City. The out-patient department of the Babies' Hospital, where the examinations were made, is not a neighborhood clinic, the patients being recruited from all parts of the city. The study covered a period of five months, from July, 1919, to January, 1920. The stools were collected at random, without reference to the condition of the child or to the symptomatology. Many stools were examined of children who attended the clinic as visitors accompanying a sick brother or sister. Some were of children who attended for vaccination. The routine procedure was to place the child on a vessel for a few minutes; if no stool was obtained, the child was given an enema of warm tap water; if this was unsuccessful, the parent was given a container and told to bring a fresh stool to the next class. The method employed in this study for examination of stools was the brine flotation-loop method as perfected by Kofoid and Barber. In an examination of 308 stools in children up to 12 years of age, 2.27 per cent. harbored parasites. There were 3.7 per cent. positive in 189 examinations of children from 2 to 12 years of age. In a group of 69 children from 4 to 12 years of age, 5.7 per cent. were positive. In another group of 189 children from 2 to 12 years of age, 3.7 per cent. harbored intestinal parasites. From this it is concluded that intestinal parasites are infrequent in New York City children living under good hygienic conditions.

2. The Vital Capacity Constants Applied to the Study of Pulmonary Tuberculosis.—Dreyer and Burrell recapitulate the procedures (described in *The Lancet*, August 9, 1919) for taking the various measurements in a study of vital capacity as follows: (1) Body weight = net weight without clothes in grammes. (2) Trunk length in centimeters was taken by making the subject sit on a level floor with the knees flexed, the os sacrum, spine, and occiput being in contact with an upright measuring standard. (3) Circumference of the chest in centimeters was taken at the nipple level in males, and just under the breasts in females, the subject being encouraged to talk and breathe naturally while the measurement was being taken. (4) The vital capacity in cubic centimeters was obtained by taking five consecutive readings with a suitable spirometer. The subject was instructed carefully and patiently how to proceed, and encouraged to make the maximum effort. Tables have been prepared, shortly to be published, giving the vital capacity, corresponding to different weights, trunk lengths, and chest circumferences, as well as the normal weight corresponding to these measurements, for males and females. It has been found that for all practical purposes people may be grouped into three classes of different vital capacity, representing conditions of perfect, medium and poor physical fitness. These tables have been used for the calculation of what the normal vital capacity should be in each case, due attention being paid to the class the subject was likely to belong to according to his mode of life. The figure for vital capacity derived from these tables is always taken as equal to 100 per cent., and the individual is said to be normal, or minus, or plus so many per cent. A general analysis is given of two hundred cases in which the vital capacity has been examined on only one occasion, and more detailed analyses of one hundred and sixteen cases in which the vital capacity has been taken on more than one occasion. It was found to increase by at least 2 per cent. in 44 cases. It was found to have decreased by at least 2 per cent. in 39 cases. It varied less than 2 per cent. in 27 cases. In the remaining 6 cases it varied—sometimes increased, sometimes decreased. From the careful analysis of the cases given in detail the following conclusions seem to the writers to be justified: 1. In cases of pulmonary tuberculosis there is a definite increase in vital capacity as compared with what should be normal for any individual, taking into account the class in which this individual should be placed according to occupation and mode of life. 2. An improvement in the clinical condition of the patient is found to be accompanied by an increased vital capacity, while an advance of the disease results in a decrease in vital capacity. The vital capacity, therefore, gives a valuable quantitative measure for the benefit, if any, which a patient receives as the result of treatment. 3. The determination of the vital capacity is useful for the classification of cases of pulmonary tuberculosis, because it is possible by this means numerically to express the injury to health (e.g. degree of toxemia) which otherwise would depend on the individual interpretation of physical signs by different observers. In this connection it should be noted that classification by physical signs alone may place a patient nearing death from an acute lesion in a high category, while another patient, with satisfactory fibrosis and extensive cavitation, likely to live for several years, may be placed in the lowest category. 4. As an aid to diagnosis a single or repeated examination of the vital capacity of doubtful cases will also prove useful. If a normal vital capacity is found in such cases, the patient is most unlikely to be suffering from pulmonary tuberculosis, whereas if the vital capacity is much decreased, the patient should be suspect, though it must always be borne in mind that other diseases may also cause a lowering of the vital capacity. 5. Finally, a systematic study of the vital capacity in its proper relationship to body size has given important information as to the beneficial effects of different treatments of pulmonary tuberculosis, and has made it possible to distinguish quantitatively the degree of improvement obtained in the several cases.

1. Clinical Observations on Jejunocolic Fistula Following Gastrojejunostomy.—Bolton and Trotter state that the frequency of the formation of jejunal ulcer following gastrojejunostomy is unknown, but has been estimated at from one to two per cent. of operations. The ulcer forms at the anastomosis, from which it commonly spreads in the jejunum, sometimes in the stomach, occasionally in both; or it arises primarily in the jejunum near the anastomosis, but sometimes at a greater or lesser distance from it in the efferent limb. A little over ten per cent. of jejunal ulcers become adherent to the transverse colon and perforate into it, thus establishing a jejunocolic fistula, or much less commonly a gastro-colic or a gastro-jejuno-colic fistula. Four such cases are reported by the writers, whose study of the literature of the subject shows that twenty-seven cases are already on record. All the cases, including those of the writers, occurred in males. The only treatment of any avail when a jejunocolic fistula is established is by operation. The aim should be, however, to prevent the occurrence of jejunal ulcer, which is the cause of the fistula. It would seem that in general the obliteration of the fistula without interference with the gastrojejunal anastomosis is the best procedure to carry out if it is possible, and there is no contraindication such as active ulceration or the presence of stricture. To secure satisfactory closure of the openings which have constituted the fistula, it is essential that the colon and jejunum be freely separated from one another, and it is desirable that a piece of omentum be put between them. If it is not possible to get the colon and jejunum well separated without encroaching on the anastomosis, then the latter must be sacrificed and the piece of stomach wall containing it excised. If a stricture is actually present or suture of the opening is likely to narrow too much the lumen or jejunum or colon, an appropriate resection will be necessary. In any case the establishment of a temporary cecostomy is of the greatest value. The sole purpose of such an opening is to prevent the accumulation of flatus in the colon above the suture line. By it the sutures are relieved from any strain and the patient is spared the discomfort and danger of post-operative distension. If the pylorus is still obstructed and it is necessary to obliterate the anastomosis, a fresh gastroenterostomy must be done or an extensive resection of the stomach, such as described by Clairmont.

7. On the Early Diagnosis of Variola.—N. B. Gwyn records briefly, with charts, his findings in the few instances, in the recent epidemic of variola in Toronto, in which he had the opportunity of making very early examination of the blood. In at least two instances he was struck by the firm enlargement of the spleen. The blood picture of small-pox, he says, is by no means clearly drawn. He appends a table showing the figures in nine cases that developed in the wards of the Toronto General Hospital. The normal and low count in all cases but one was a striking feature, while

in this one case the drop of the leucocytes during the fever wave is evident. Of particular interest is a case of pernicious anemia, in which an abnormally low white blood count (2,200) was not increased during the whole of his pre-eruptive stage. The relation of the count to the termination of the primary fever is indicated in the table. No rise of leucocytes takes place during the period of primary fever. In two of the cases in the series in which the condition of the spleen was early and carefully investigated, the spleen was enlarged, firm, and presented a rounded edge. So marked was this enlargement in one case that the fingers of the palpating hand could feel the border without the respiration usually asked for. The firmness of the organ in a second case was like that felt in malarial infections. In this case the fever, absence of backache, and low leucocyte count suggested typhoid fever, but the solid impression given by the spleen was noted as unusual for early typhoid. Two complete primary fever waves were given. Four days seems to be the definite duration of the fever of the early stage. The day of the appearance of eruption is noted.

3. The Diagnosis and a New Treatment of Decensus of the Stomach.—Louis G. Frumson, after discussing the etiology, symptomatology and diagnosis of ptosis of the stomach summarizes his observations in part as follows: The stomachs which are low because of stretching and thinning of the gastric walls, and which have a greatly increased capacity, are usually indebted to an organic lesion for their plight, while the stomachs which are low, but which have not increased in capacity, which occupy the left side of the abdomen and possess a sharply angulated "V" shaped lesser curvature, have for their sponsor perverted physiology or abnormal function. The treatment of the organic is obvious and necessitates the removal of the underlying pathological condition before the stomach may be returned to its usual site in the peritoneal cavity. Almost without exception, surgical intervention is the means toward this end. The treatment of the functional, however, allows a broader field for the ingenuity of the physician, but even here the diet, habits, and domestic life of the individual must be thoroughly investigated if permanent relief is to be hoped for. The writer has tried nearly all of the bandages and binders offered for the relief of this condition, but has always found a disadvantage of some kind, and has abandoned them, one by one. For the past two years he has used a strip of elastic webbing about seven yards long and six or eight inches wide. This is inexpensive and does not retain the excretions of the skin. The elastic bandage is applied in the following manner: The patient lies supine and raises the buttocks about six inches from the table or bed, with the head remaining in position on the bed. This places the patient in a semi-Trendelenburg position. Pushing the abdominal contents towards the diaphragm with the right hand and at the same time securing the end of the bandage with the right hand, the bandage is wrapped around and around the abdomen, considerable tension being made on it all the while. The first encircling of the belly wall should be begun at the level of the pubis and each ascending turn should overlap the previous one by an inch or two; the proximal end, which should be a few inches above the umbilicus, being fastened with a safety pin. The writer recommends that the bandage be worn all day and taken off when the patient retires.

The New Laws of Hereditary Syphilis.—Carle has studied the laws of inherited syphilis for the past 14 years in the effort to formulate them anew and is satisfied that his interpretation published in 1906 is correct and will stand every test of clinical experience. The original Colles law was as follows: an infant procreated by a syphilitic father does not in the vast majority of cases infect its mother, who retains the appearance of health and may nurse her infant with impunity. The author would restate this law as follows: a mother who gives birth to a syphilitic infant which develops the lesions of secondary syphilis shortly after birth is always syphilitic herself despite her appearance of health. Hence she may of course nurse her infant with impunity, but she should nevertheless be treated for her disease exactly as should any other syphilitic. Exceptions to Colles's law do not exist, but rest on false observation. Profeta's law was originally as follows: a child recognized as sound although born of a syphilitic mother does not contract syphilis from nursing the mother or other contact. Such immunity however is not permanent. The author edits this law as follows: such a child is usually syphilitic despite its apparent health and in such a case cannot of course contract the disease. In a minority of cases however such children escape infection and show a negative Wassermann. The seroreaction determines the status of these infants. Fournier's law, the third to be considered, was originally expressed as follows: a syphilitic *fetus in utero* may by the intermediation of the placenta vessel contaminate its mother, who develops secondary syphilis during gravidity. This law, which was also upheld by Finger, the author discredits entirely because of the underlying fallacy that a primary lesion has not preceded the eruption. From our knowledge of the elusiveness of the chancre in women and its failure to leave traces we cannot be sure that the woman has not been infected in the ordinary way. The author disbelieves in syphilis of the ovum or conceptional syphilis, save that a syphilitic father may beget a dystrophic child. A spirochetal infection of the ovum he regards as unproven and even untenable.

Idiopathic or Neurogenic Priapism.—A case of this condition which was reported in 1919 has been abstracted in the *Brazil Medico*. The patient was a man of 28 who entered a neurological clinic to obtain relief from priapism. The subject appeared to be in perfect health and the erection had failed to yield to coitus or other remedy. The organ was rigid and turgid in the highest degree and with the testicles was very sensitive to touch. In the clinic he was subjected to all possible tests, but there could be found no reason for the behavior. All forms of sedation including chloroform anesthesia were tried one after the other, but none of them afforded any relief. But finally, after the condition had persisted for 28 days, it slowly subsided under the galvanic current. Eight days were required for complete subsidence. Six months before the major attack the subject had had priapism lasting three hours without apparent cause. While in the clinic his general condition became poor either as a result of his disorder or for some unknown reason. Sleep was poor and he lost his appetite. As a result of the prolonged priapism the penis even while normally relaxed had increased in size.—*Brazil Medico*.

Book Reviews.

THE TREATMENT OF SYPHILIS. By H. SHERIDAN BAKETEL, A.M., M.D., Fellow of the American College of Physicians; Lt. Colonel, Medical Reserve Corps, United States Army; Professor of Preventive Medicine and Hygiene and Lecturer on Genitourinary Diseases and Syphilis in the Long Island College Hospital, Brooklyn; Attending Syphilologist and Chief of Clinics, Volunteer Hospital, New York; Genitourinary Surgeon to the House of Relief of the New York Hospital; Medical Director of the H. A. Metz Laboratories; Member of the American Urological Association, etc. New York: The MacMillan Company, 1920.

THE outstanding feature of this volume is the careful and detailed description of the technique of intravenous administration of the arsenical preparations in the treatment of syphilis. All reference to the history, etiology, and pathology of the disease is omitted. Due attention is accorded to the chemistry and chemotherapy of arsenic compounds, their indications, contraindications, and efficiency. The author avoids polemics and states his own opinions in straightforward and sincere manner. He generously quotes from contemporary writers and gives due credit to other workers. This book is of especial value to the beginner in intravenous therapy.

MENDERS OF THE MAIMED: The Anatomical and Physiological Principles Underlying the Treatment of Injuries to Muscles, Nerves, Bones, and Joints. By ARTHUR KEITH, M.D. (Abdn.), F.R.C.S. (Eng.), F.R.S.; Conservator of the Museum and Hunterian Professor, Royal College of Surgeons, England. London: Henry Frowde—Hodder & Stoughton, New York; Oxford University Press, American Branch, 1919.

THIS book is based on a series of lectures given at the Royal College of Surgeons of England in the winter of 1917-18 on "The Anatomical and Physiological Principles Underlying the Treatment of Injuries to Muscles, Nerves, Bones and Joints." The title of these lectures fairly states the ground covered in so far as instruction of a surgical nature is concerned; but a large part of the text is also given over to descriptions of the work and biographical sketches of the men, such as John Hunter, Hilton, Thomas, Little, Stromeyer, Sayre, Syme, and many others, whose discoveries, researches, and teachings laid the foundations for the development of orthopedic surgery; while there are also many pages on the work of Wolff, Ollier, Macewen, Albee, and others who have laid the foundations for or actually developed bone-graft surgery as it is practised to-day. This book will appeal not only to the orthopedist, but also to those practitioners of medicine and surgery who are interested in the history and development of orthopedic principles and currently accepted methods of treatment. The author has an easy and graceful diction, so that reading the book is soon found to be a pleasure rather than a task.

SEXUAL IMPOTENCE. By VICTOR G. VECKI, M.D., San Francisco, Cal. Sixth Edition, Revised. Philadelphia and London: W. B. Saunders Co., 1920.

THIS little book impresses one as being a thoroughly scientific and logical presentation of this subject. The author has read the books, he has had a vast experience with patients, and he has reasoned clearly. Not the least to be commended are his remarks on continence, where he refuses to adopt the moralistic tone which too often vitiates the views of urologists, and gives us a plain comprehensible opinion, stating the arguments pro and con. The hypercritical will find in the text much at which to cavil on the grounds of purism, occasionally awkward expressions occur which in some cases render his meaning a trifle obscure, as, *e.g.* "In acute urethritis the fuchsin injections should be made every three days once, gradually increasing the strength of the solution used" (p. 289), but the thorough and practical nature of the work as a whole far outweighs any such petty blemishes. That this book is now in its sixth edition is in itself an argument of its value, but even should the present volume stand without its five predecessors we would not hesitate to predict a large audience for it.

MANUAL OF DISEASES OF CHILDREN. By JAMES BURNET, M.A., M.D., M.R.C. P. (Edin.) Physician for Diseases of Infancy and Childhood to, and Physician in charge of The Child Welfare Clinic at, the Marshall Street Dispensary, Edinburgh; A Vice-President of the Royal Society of Medicine (Section for the Study of Diseases in Children); and Late Examiner in Materia Medica and Therapeutics to the University of Aberdeen; Author of the Nursing of Sick Children, the Pocket Clinical Guide, etc., etc. Second Edition. New York: William Wood & Company, 1920.

THIS manual is intended as a pediatric guide. It describes the method of examination of sick children and gives interesting points of difference between children and adults. The chapter dealing with the diseases of the newly-born is instructive. In the chapter on nutrition we find the author condemns the use of dried milk and holds that its indiscriminate use is wrong. He advocates a careful study of the infant before giving haphazardly any advertised food. The author has had excellent results with citrated milk feeding. Empiric methods of feeding are advocated. The illustrations are pratical and excellent. The book will serve as an excellent guide to one desiring up to date pediatric suggestions.

PRINCIPLES AND PRACTICE OF INFANT FEEDING. By JULIUS H. HESS, M.D., Professor and Head of the Department of Pediatrics, University of Illinois College of Medicine; Chief of Pediatric Staff, Cook County Hospital; Attending Pediatrician to Cook County, Michael Reese and Englewood Hospitals, Consulting Pediatrician Municipal Contagious Hospital, Chicago. Illustrated. Second Revised Edition. Philadelphia: F. A. Davis Company; London: Stanley Phillips, 1919.

THAT a second edition of this work has been called for within one year is ample proof of the interest in and value of infant feeding. There are many new points in this book which are of value to the general practitioner. The chapter dealing with the metabolism of fats and proteins is very instructive. On pages 20 and 21 we find a very interesting discussion of the vitamines. On page 24 in the discussion of stools the author states that thin watery stools must always be taken seriously, but that the same cannot be said of green, curdy stools, which are not infrequently seen in thriving breast-fed infants. These curds are almost invariably due to fatty acids and soaps. These stools are perfectly consistent with a normal growth and well-being of the baby. It is not an indication for a change of food.

The author favors the use of saccharose (cane sugar) for his milk modifications. In addition to the carbohydrates, the disaccharides such as maltose. and the polysaccharides, represented by the cereal flours and dextrine, are advised.

In the past it was taught that a study of the stool gave definite information for the differential diagnosis of the gastrointestinal disease, but experience has taught us that conclusions are of value only when based upon stool examinations in conjunction with a careful study of the diet and the clinical examination of the infant.

The nature of the dominant organisms which develop in diets rich in carbohydrates varies with the carbohydrate itself. Bacillus bifidus is more commonly predominant when lactose is the sugar fed without an excess of protein. If maltose or dextrose is substituted for lactose under the same conditions, bacillus acidophilus is very frequently the more prominent.

The greatest change noted in this little book is in the chapter on artificial feeding in that an absolute relationship between the quantity of the individual food elements of the diet and the requirements of the infant per pound body weight of fat, protein, carbohydrate salts and water for growth and development are made the basis for preparation of diets. This establishes a fixed basis for comparative quantitative studies of relation of diet to growth and development independent of the size and frequency of feedings, and the percentage composition of the mixture.

Society Reports.

AMERICAN GYNECOLOGICAL SOCIETY.

Forty-fifth Annual Meeting, Held at Chicago, Illinois, May 24, 25, and 26, 1920.

THE PRESIDENT, DR. ROBERT L. DICKINSON, NEW YORK, IN THE CHAIR.

Analgesia and Anesthesia in Labor.—Dr. EDWARD P. DAVIS of Philadelphia stated that the best quality of ether, skillfully administered, was successful in the majority of cases of spontaneous labor during the second stage. If given at the height of the pain, quickly removed so soon as the pain subsided, it stimulated and did not retard labor, but the moment when expulsion occurred a few deep inhalations without air would render the patient insensible to pain, although capable of comprehending sensations of feeling, of hearing, or often of sight. The mother roused easily after delivery and required no anesthesia while the placenta was separating. For the insertion of stitches immediately after labor ether properly administered with oxygen was comparatively safe and efficient. He had seen no evidence that such use during the stage of expulsion injured the fetus. It was true that ether was inflammable, that some patients were excited by it, that it was irritable to the bronchial tubes and kidneys, and that it was difficult to anesthetize some patients with ether, but if skillfully administered it was usually successful and its combination with oxygen rendered it in his experience the safest of obstetric anesthetics. The modern anesthetizer should be prepared to use nitrous oxide and oxygen, ether and oxygen, chloroform with or without oxygen, changing, if necessary, from one to the other of these during a prolonged operation. In special fields of surgery the invention of special apparatus had made anesthesia vastly more accurate and successful. For the obstetrician analgesia or anesthesia, skillfully given, made for more accurate diagnosis during labor and for the successful management not only of spontaneous and normal parturition, but of complicated conditions. It was a familiar fact that recovery from parturition was greatly delayed by exhaustion during labor. In this regard modern analgesia and anesthesia was one of the greatest advances made by modern obstetric science. One must not forget the considerable fatal mortality and morbidity produced by prolonged birth pressure and by unregulated and violent expulsive efforts. The danger of asphyxia to the fetus during labor by analgesia and anesthesia was vastly less than the danger of cerebral or other hemorrhage from birth pressure and the avoidance of this latter complication was greatly enhanced by obstetric analgesia and anesthesia.

Induction of Labor; Indications and Methods with Special Reference to the Use of Pituitary Extract.—DR. BENJAMIN P. WATSON of Toronto, Ontario, said that Blair Bell in 1909 was the first to employ in practice the results of experimental investigations carried out on the extract of the pituitary gland up to that time. Since then a great mass of literature had accumulated on the subject. It was universally recognized that it was a most valuable agent for accelerating the second stage of labor when delay was due to feeble uterine contraction. In most of the articles which had appeared the reader was warned against using it for the induction of labor or, before the cervix was fully dilated. He had used it extensively for the induction of labor and during all stages of labor, and had never had any bad results. In 1913 he recorded 3 cases in which he had successfully induced labor by its means. One of those was at the eighth month, one at full term, and one at three weeks post term. He stated that the method was worth an extended trial and he thought that his further results bore this out. The method used was to begin with a dose of one-half to one c.c. administered intramuscularly with a long needle. In most cases uterine contractions commenced in about ten minutes and increased in severity during the next twenty minutes. At the end of this time the second injection of one-half c.c. was given. If, after a time, the contractions tended to weaken, or to come at longer intervals, the dose was repeated. As many as six or eight doses might thus be given at intervals of about one-half hour. The important point was to administer a further dose before the effects of the previous one had entirely passed off. The effects from a single dose appeared only to last for about one-half hour and there was no cumulative effect. Sufficient doses must, therefore, be given to keep up uterine contractions sufficient to produce a certain amount of opening up of the cervix. When the cervix had begun to open and the membranes to bulge into it the uterine contractions would continue without the further administration of the drug. The failures which he had in the beginning were the result of not pushing the dosage far enough. He had found it perfectly safe to give eight or ten ½ c.c. doses at half-hour intervals. In 19 multiparæ the average duration of labor was 19 hours as contrasted with 18 hours as an average in 18 multiparæ. With the bag method the average time elapsing before labor began was 13 hours and the average duration of labor was 10 hours. This number, of course, was very small and not sufficient to draw conclusions from. With quinine alone, in 25 cases the average time elapsing from the last dose to the definite onset of labor was 7 hours, while the average duration of labor was 9 hours, 7 for multiparæ and 11 for primiparæ. With pituitrin alone in a total of 18 cases the average time elapsing between the first dose and the definite onset of labor was 2 hours. The average duration of labor was 10 hours, 16 hours for 5 primiparæ and 9 hours for 13 multiparæ. With quinine and pituitary extract, in a total of 62 cases 53 were successful, 9 were totally unsuccessful. Six of the successful cases required repetition of the routine before labor began. In the 53 successful cases the average time elapsing between the first dose of pituitrin and the onset of labor was 2 hours and the average duration of labor was 10 hours; 14 hours for 23 primiparæ and 7 hours for 30 multiparæ. The labors in the quinine and pituitrin cases were spontaneous except in 4 cases in whom forceps were used when the head was on the perineum. In the total of 53 there were four stillborn babies. Recently two of his colleagues, members of his staff, J. G. Gallie and W. A. Scott, had recorded a series of 65 cases in which they used pituitary extract alone for the induction of labor. Out of this total 55 were entirely successful. The average number of doses given was three, the average duration of labor was 7 hours. There was one fetal death 28 hours after delivery from atelectasis. The delivery was normal in 45, by forceps in nine and by version in one. Taking these results along with the ones which he had recorded, he thought we must recognize that the method had a definite place in obstetrical practice and should be considered before other methods were adopted. It had very special advantages in cases of slight disparity between the head and pelvis, as it did not in any way prejudice the cesarean operation should it prove to be necessary—an argument which could not apply to the bougie or bag method.

The Induction of Labor at Term.—Dr. CHARLES B. REED of Chicago said that labor could be inaugurated by quinine and pituitrin, by castor oil and quinine, by the modified de Ribes bag, or by both. The castor oil acted in about two cases out of five and most reliably when the patient was a little bit past the calculated date. The Vorhees bag in his experience was the most dependable and was, therefore, the favorite agent at his hospital. The patient's bowels should receive attention the night before and in the morning the external genitalia was given a careful obstetric preparation. Assemble and sterilize by boiling 20 minutes a modified de Ribes bag No. 4 (Vorhees), a Simon speculum or vaginal retractor, a pair of long Pean forceps (dressing forceps would serve), two pairs of vulsellum forceps, two pairs of compression forceps, a Goodell dilator a tenaculum forceps, a hand bulb syringe with glass tubes and rubber connections for the bag or a large piston syringe. The bag and accessory apparatus must be tested for defects before using. The patient prepared as for delivery was placed upon the table in exaggerated lithotomy position with legs held by assistants or by stirrups. The vagina was retracted, a smear made from the cervix and the mucous membrane wiped clean with pledgets.

Anesthesia was only occasionally necessary even in primiparæ. One lip of the cervix was seized by the volsellum and brought down. If the bag had been properly prepared the os would admit it originally without dilatation. The bag must be emptied of residual air and the flat end pulled out. It was next rolled into a compact mass like a cigarette and seized by the Pean forceps so that the tips extended just to the largest diameter of the rolled bag. After annointing the bag with sterile glycerin the bag was passed into the cervix with the concavity of the forceps turned toward the patient's left leg and as it entered the os the concavity was turned upward one-quarter of a circle so that when the maneuver was completed the curve of the instrument conformed to the flexure of the uterus. The lock of the introducing forceps was then released; tube of the bag was connected with the filling apparatus, and the sterile solution (lysol, boric acid, or plain water) was forced slowly into the bag. One should not overfill by force or the bag would break. Tension in the tube of the bag and the feeling of resistance to the injection were signs of fullness to the experienced operator. If uncertain of the technique, a measured amount of fluid might be used. A piston syringe of tested size would also serve to inform the operator when the capacity of the bag (6 oz.) had been reached. The Pean forceps were removed as soon as the bag was sufficiently filled to keep it from slipping out. The compression forceps should now be snapped on the tube, the vulsellum removed from the cervix, and the syringe disconnected. The tube of the bag must be tied strongly with tape, and the compression forceps removed. Two sterile pads were placed on the vulva, one on either side of the tube, the stirrups were then removed and the patient pulled up in the bed. The bag might break from overfilling or being insufficiently filled might slip out of the cervix before the uterine contractions began. If so, another bag should be inserted. If the pains did not start within an hour a weight of one or two pounds was attached by a tape to the protruding tube and passed over the foot of the bed. Usually in from five minutes to half an hour the contractions began and labor was under way. In a variable period, rarely more than four hours (three hours and twenty minutes in his series), the bag was expelled by strong pains, the dilation was practically complete, and the head followed the bag down into the pelvis, the membranes ruptured and the second stage began. From then on the case was managed according to general obstetrical principles. The tedious exhausting and painful first stage had been definitely shortened. The bag acted as a mechanical aid to cervical dilatation, a dynamic stimulant to the contractions and preserved the membranes from injurious pressure until physiological rupture occurred. When the membranes had been accidentally ruptured by the insertion of the bag no attempt should be made to pull on it to mark advancement lest it came out and by suction bring down the cord. When the bag came out after accidental rupture of the membranes at the time of insertion it was good practice to make an internal examination to discover the presence or absence of a prolapsed cord. In the series of 200 cases hitherto reported he had multiparæ 114 and primiparæ 86. The average duration of labor was 7 hours and 56 minutes, the longest labor was 30 hours, and was due to a tough inelastic cervix. Two others were in labor 28 hours from cervical conditions. In one the cervix was a mass of cicatricial tissue. The shortest labor in a multipara was 55 minutes and in a primipara 60 minutes. The bag broke while being filled or shortly after insertion nine times. Another bag was introduced four times. The membranes were ruptured by the insertion of the bag seven times; in one case intentionally for hydramnios. The bag was expelled in an average period of 3 hours and 20 minutes. The longest detention was nine hours; the shortest was 10 minutes. Two mothers died. One had myocarditis associated with a marginal insertion of the placenta. Her labor lasted only an hour and a half and was accompanied by a normal amount of hemorrhage only. Death came two hours after the delivery. The other had pneumonia and died eight days after labor. In no case did the bag fail to inaugurate contractions nor the woman to deliver.

The Prophylactic Forceps Operation.—Dr. JOSEPH B. DE LEE of Chicago said that the prophylactic forceps operation was the routine delivery of the child in head presentation when the head had come to rest on the pelvic floor and the early removal of the placenta. Primiparous labors and those where the conditions of the soft parts approximated a first labor, were treated by this method, which really comprised more than the actual delivery of the child. It was a rounded technique for the conduct of the whole labor, with the defined purpose of relieving pain, supplementing and anticipating the efforts of nature, reducing the hemorrhage, and preventing and repairing the damage. Sir J. Y. Simpson had said that labor, in the intention of nature, should be normal, but that in a large proportion of cases it was not so. So frequent were these bad effects, that he had often wondered if nature did not deliberately intend women should be used up in the process of reproduction, in a manner analogous to that of the salmon, which died after spawning. The radical interference with the mechanism of the third stage was intended to reduce the amount of blood lost, shorten the anesthetic period and reduce the danger of infection from retained blood clots and membranes and insufficient uterine contraction. He freely admitted that this method of treating labor was a revolutionary departure from time-honored custom and must have really sound scientific basis for recommendation. This it had. *First*, it saved the woman the debilitating effects of the suffering in the first stage and the physical labor of a prolonged second stage, and in the modern nervous inefficient product of civilization, this was becoming more frequently necessary. The saving of blood had much to do with the quick and smooth recoveries he had observed in his cases. In the combination with morphine and scopolamine in the first stage, gas or ether in the second stage and operative delivery, one had robbed labor of most of its horrors and terrors, and the increase of the population ought to be thus favored. *Second*, it undoubtedly preserved the integrity of the pelvic floor and introitus vulvæ and forestalled uterine prolapse, rupture of the vesicovaginal septum and the long train of sequelæ. Virginal conditions were often restored. *Third*, it saved the babies' brains from injury and from the immediate and remote effects of prolonged compression. Incision in the soft parts not alone allowed shortening of the second stage, but it also relieved the pressure on the brain and would reduce the amount of idiocy, epilepsy, etc. The easy and speedy delivery also prevented asphyxia, both its immediate effects and its remote influence on the early life of the infant.

The Value of the Wassermann Reaction in Obstetrics Based Upon the Study of 4,547 Consecutive Observations.—Dr. J. WHITRIDGE WILLIAMS of Baltimore said that 4,000 of the women were delivered between the 28th week of pregnancy and full term—1,839 whites and 2,161 blacks. In the series a positive Wassermann was noted in 421 cases, an incidence of 4.2 per cent.; 2.4 per cent. in whites and 16.29 per cent. in blacks; 302 children were born dead or died during the two weeks following delivery, and 102, or 34.4 per cent. death was proved to be due to syhpilis. Study of the 421 positive cases showed (1) that the presence of a positive Wassermann did not necessarily mean the birth of a syphilitic child; and (2) that efficient treatment instituted by the middle of pregnancy gave almost ideal results as far as the child was concerned. Observations showing that a negative maternal Wassermann did not necessarily imply the absence of syphilis, as shown by positive autopsy findings in 22 children. Study of the significance of the fetal Wassermann at birth and a comparative study of the diagnostic value of the Wassermann reaction and placental findings, also a brief discussion of the applicability of Colles's law was undertaken.

Extraperitoneal Cesarean Section.—Dr. JOHN A. MCGLINN of Philadelphia stated that extraperitoneal cesarean section operations could be divided into two general types: (*a*) The true extraperitoneal in which the peritoneal cavity was not invaded at any stage of the operation. This operation would be referred to

as the extraperitoneal. (*b*) The transperitoneal in which the peritoneal cavity was opened and subsequently isolated by attaching the parietal and visceral peritoneum and the uterus opened in this artificial extraperitoneal space. This operation would be referred to as the transperitoneal. The advantages of the two types of extraperitoneal operation might be summed up as follows: (1) The peritoneal cavity not being opened was isolated from the field of operation. The danger from infection was less and therefore a better operation in the infected or supposedly infected case. (2) If the uterus ruptured at the site of the incision in subsequent pregnancies or labors it was an accident of no material consequence. (3) There was no danger from the formation of peritoneal adhesions. (4) The scar was not unsightly and the possibility of incisional hernia *nil*. (5) There were no postoperative intestinal complications. (6) Hemorrhage during the operation was slight. His own feeling was that the Beck operation with thorough protection of the peritoneal cavity and perfect peritonealization of the uterine incision was superior to the transperitoneal operation as a routine procedure. While theoretically it was not as efficient as the extraperitoneal method, practically on account of the many disadvantages of the latter, it was the better operation.

Sterility in the Female; a Report of Operative Cures.—Dr. CHARLES G. CHILD, JR., of New York City said that in his series of cases the average period of sterility was three and one-half years. One case of seven years' duration was cured in 10 months. The average time from operation to the birth of the first child was 15.3 months, while seven patients gave birth within one year after operation. Seven of these patients were unconditionally sterile due to tubal occlusion, and these subsequently bore eight children—quite a respectable sized family—that owed their appearance in the world absolutely to conservative surgery. These 11 women operated upon had, to date, borne 16 living children, and eight were still in the child-bearing period. Such results as had been obtained in these cases should go far towards creating in the surgeon added respect for the art he practised, and a firmer belief in the value of conservative gynecology.

A Neglected Form of Cervical Endometritis.—Dr. HENRY T. BYFORD of Chicago stated that as a result of acute cervical endometritis a permanent exudate was sometimes left about the internal os uteri which for descriptive purpose he called a constriction ring, although in reality it was merely a greater thickness of the mucosa at that point. This constriction ring not only produced the characteristics of stenosis in many cases but gave rise to the ordinary symptoms that were usually attributed to endometritis, such as backache, reflex stomach disturbances, malaise, dysmenorrhea, intermenstrual pain, menorrhagia and sterility. The number and severity of the symptoms varied greatly in different patients, depending in part upon the interference with the patency of the lumen, the chronicity and the associated pelvic conditions, and partly upon the patient's general resisting powers and nervous habits. The diagnosis was made by means of the sound which detected a tender area at the internal os and which caused more or less bleeding. In the more chronic cases firm pressure exerted by a dilating wound produced a slight discharge of inspissated mucus which adhered to the sound. The treatment called for gradual progressive dilatation with round dilators under the strictest aseptic and antiseptic precautions, and later stimulating applications of iodized phenol. The occasional failure of an Emmet trachelorrhaphy to cure the symptoms was laid to a persistence of such an exudate at the internal os.

The Treatment of Suppurating Wounds Following Abdominal Section.—Dr. THOMAS J. WATKINS of Chicago said that no sutures were removed on account of suppuration except when they cut deeply into the tissues, and no drains were inserted. No probing was permitted. Moist boric acid dressings were placed over the wound as soon as signs of suppuration appeared and were continuously applied until excessive redness disappeared. The moist dressings were used to keep the wound secretions from desiccating and to thus promote drainage. Experience had shown that a large amount of drainage would take place through very small openings when thus treated, that the drainage would be efficient, and that the suppurating surfaces, by virtue of atmospheric and intraabdominal pressure, would keep in relative apposition. The author had used this treatment for about fifteen years and had found that the wounds healed quickly; that the treatment was painless; that the patient was not unnecessarily disturbed mentally, and that the ultimate strength of the abdominal wall was seldom injured by the suppuration. When the discharge ceased no open wound remained to heal by granulation. Antiseptic solutions were not employed, as they injured the tissues more than they harmed the bacteria. Irrigations, drains, and the like did much damage to the delicate tissue repair which was present in the healing wounds. Photographs were presented of wounds which had suppurated and showed no evidence that there had been any suppuration. It was not uncommon for patients who had had suppurating wounds to entirely recover, and leave the hospital at the end of the third week after operation.

Errors in Gynecological Diagnosis Due to Misplaced Organs.—Dr. REUBEN PETERSON of Ann Arbor, Mich., drew the following conclusions: (1) Mistakes in gynecological diagnosis arising from misplaced organs are not uncommon as shown by the literature in which only a small proportion of such mistakes is probably recorded. (2) Such errors in diagnosis arise from either carelessness or preconceived ideas of diagnosis whereby important facts in the history and equally important physical findings are either overlooked or ignored. 3) Such diagnostic errors can be averted by greater care in systematically considering with a free mind the facts in the case relating to the history and physical findings provided the latter be obtained through the employment of the most modern methods of examination. (4) In every case a preoperative diagnosis should be made and recorded in order to profit by mistakes revealed at the operation or autopsy.

The Gynecological Problem in Industrial Medicine.—Dr. HARRY E. MOCK of Chicago said that the scope of industrial medicine involved the supervision of the health of employees in industry and other problems connected with the factor of human maintenance. It included the prevention of diseases and accidents; the constant supervision of the physical conditions of the employees by medical examinations and frequent conferences; the adequate medical and surgical care; industrial sanitation and nursing service. Comprehensive medical systems had been installed in a great many of the large industries of the country. Where women were employed this health supervision had given a great opportunity to study many gynecological problems and their effect upon the efficiency and desirability of women employees in industry. A common cause for absenteeism among women workers was dysmenorrhea. Personal observations of this condition among several thousand women employees in a large industry were given extending over a period of several years. Other gynecological problems met in industry among women employees included the frequency of venereal diseases where complete medical examinations of women were made; the frequency of pregnancy among girl workers and how this problem should be met; the effect of dress, diet, and habits upon the health and efficiency of women workers; the need of convalescent homes in large cities for the women workers. Industrial medicine presented a wonderful opportunity for studying certain medicosociological problems as related to the large group of employees.

Hemorrhages Into the Pelvic Cavity Other Than Those of Ectopic Pregnancy.—Dr. RICHARD R. SMITH of Grand Rapids, Mich., said that although ectopic pregnancy was by all odds the most frequent cause of hemorrhage within the pelvic cavity, it occurred occasionally from other causes. The most frequent source of such hemorrhage was the ovary. For clinical purposes they might be conveniently divided into three groups: (1) Caused by a ruptured Graafian follicle or corpus luteum which occurred most frequently in young women, and in which the symptoms rather closely resembled an ectopic pregnancy. Many cases had been operated upon also for supposed appendicitis. Blood might be found in lesser amounts

or in amounts large enough to cause grave symptoms. A microscopical examination ordinarily showed a normal Graafian follicle or corpus luteum. (2) The second group was not uncommonly designated as hematoma ovarii. Here one was dealing with a distinctly pathological condition. This might be evidenced with hematomas into the Graafian follicles, with secondary changes following in the ovarian structure. This condition was rather frequently associated with fibroids or with some inflammatory trouble with the appendages. In other cases no such association apparently existed nor was the cause clear. In young women it was sometimes the cause of severe dysmenorrhea. (3) A group of hemorrhages associated with ovarian tumors (cystic or solid) of some size in which the bleeding occurred into the tumor or from it into the peritoneal cavity. Such bleeding tumors were commonly the seat of a twisted pedicle or of inflammatory adhesions; also a ruptured pedicle had been the cause. Although the tube might on rare occasions give rise to hemorrhage without the cause being evident, in most cases the reason for such hemorrhage was apparent. A tube involved in the twisted pedicle of an appendage was a good illustration of such hemorrhages; occasionally it was found associated with the thickened tubes of an old infection. Such hemorrhages were small in quantity in the reported cases and the condition should be easily differentiated from ectopic pregnancy. Intraperitoneal hemorrhages from fibroid tumors formed a very interesting group. Wallace reported 17 collected cases and Gerstenberg one. The hemorrhage was often severe and the mortality had been very high (35 per cent.). They occurred from dilated veins or from a rupture of the tumor itself.

Presidential Address.—Dr. ROBERT L. DICKINSON of Brooklyn, N. Y., delivered this address in which he said that in all other departments of medicine and surgery the war made an inventory of men and methods. Gynecology should now conduct a complete self-survey. The specialty was limited but large, the procedures being few, yet gynecological operations, as studied in clinical congresses or in daily operation notices of large cities, omitting lesser operations, were shown to comprise one-fourth of surgery. Operation was required in less than one-tenth of patients with disabilities peculiar to women, obstetrics being excluded. The future problems that gynecology was alone qualified to solve were considered. The first was its own portion of a standard nomenclature, whereupon the new census volume was presented. The operation nomenclature was under way. Standards were defined as the best present practice, widely studied, fairly epitomized, succinctly written down, warily applied, both flexible and progressive. There was need of taking stock of obstetrical and gynecological clinics. The lack of leaders was deplored, one cause shown by the war census being a want of hospital connection, only one medical man in 28 and one surgeon in four having such connection. Therefore, deliberate selection, training, full knowledge concerning specialists, teaching centers for the future were urged, and the carrying of obstetrical education directly to the practitioner in his own locality. Women should be given hospital opportunity, so that American women might prove themselves as good as British. What were some of the sociological problems? Sterilization of women by simple means, with tests of tube patency; artificial impregnation; contraception; the definition of normal sex life; the doctor's section of sex instruction; and extension of routine pelvic examination before marriage, and the harder forms of industry, the result of hard labor and schooling. He advocated a journal under the auspices of the society, and collaboration in a finely illustrated standard type of student's manual; also gynecological centers in libraries and museums, including slide library, loan charts, and a studio. Finally, action was considered looking toward certification of specialists, such certification to hold good some ten years at a time.

The Development of Prenatal Care and Maternal Welfare Work in Paris Under the Children's Bureau of the American Red Cross.—Dr. FRED L. ADAIR of Minneapolis said that pre- or ante-natal care was that part of a public health program which had as an ultimate object the beneficial influencing of the health of the offspring by surrounding the mother with proper conditions during the period of pregnancy. Any complete health and social welfare program should include two public welfare activities, i. e., maternal and infant welfare, which were closely related and should be very carefully coordinated. These activities were intimately bound up with the family and concerned particularly the mother and child. While these two subprograms were more or less closely related to all the other public welfare work, they had more points of contact with each other than with the rest of such activities. From an administrative viewpoint these two activities should be comprised in a maternal and child welfare program, but from a medico-social standpoint the work should be handled by experts in the different lines of work. The objects of the maternal welfare program were: (1) To develop healthy parents, especially mothers who were intelligently trained; (2) To bring them through life to maturity capable of having and rearing normal children; (3) to reduce the maternal, fetal and newborn morbidity and mortality to the lowest possible level; (4) to leave the mother with a desire and capacity to bear and rear children properly in a sufficient number and of such a quality as not only to maintain the integrity of the human race, but to constantly improve its character. The family should be protected from various detrimental influences by education, legislation, and proper help and advice. This meant that each family should have a normal economic status, proper housing, etc., good sanitary surroundings, proper advice, and care in case of physical or other needs resulting from disease, economic reverses, or distress of any kind. Some of the medical problems which vitally affected the individuals and the family were those dealing with tuberculosis and venereal diseases. These activities were very closely allied to maternal welfare work. The educational program involved the education of adolescents along proper sex lines. This necessitated careful study and thought in laying out the educational program as well as in selecting those who were to give this instruction. The legislative program included those laws which were designed to protect the family unit in health, economic independence and happiness, or to prevent any invasion by medical or social disease. The relief of social distress and disease was not less important than the cure of physical ailments and diseases. For the happiness and well-being which could be brought to the individual mother and those associated with her by intelligent guidance, sympathy and help were unmeasurable.

The Importance of a Follow-up System.—Dr. GEORGE W. KOSMAK of New York City introduced the question of whether a recently delivered mother in either private or hospital practice was accorded as much attention in a follow-up sense as a patient recovering from medical and surgical illness. During the past decade the development of prenatal care might be regarded as one of the most important advances in obstetrics. In view of the liability to injuries resulting in invalidism remaining unrecognized in the usual postpartum examination, a discharge of the patient should not be made for at least three months after the birth of the child. During this interval at least two or three examinations of the patient should be made. It was possible to treat minor traumatic and other lesions during this period and avoid later complicating conditions resulting in invalidism. A survey of 48 American maternity hospitals showed that 36 of this number maintained some sort of follow-up system, but in the majority of the latter the patients only returned if abnormalities developed. The admission was made by practically all observers that a follow-up system for obstetric patients was not only desirable but necessary. Certain difficulties must be acknowledged in instituting such a system, but with the better education of the patient the realization of the need would become apparent to her and her family. A regularly organized postpartum clinic should be part of the equipment of every maternity hospital and in connection with the same an organization of social service workers or follow-up nurses to visit the patients in their homes was essential. The necessity of more prolonged postpartum observation should be included in every scheme of hospital stand-

ardization and the shortcomings of institutional work in this field applied with equal force to private patients. The advisability of some form of maternity insurance might do a great deal to obviate some of the difficulties connected with the scheme of more prolonged postpartum care of obstetric patients.

Operation or Radium for Operable Cancer of the Cervix.—Dr. WILLIAM P. GRAVES of Boston gave a comparative analysis of personal cases treated by operation and by radium. Personal experiences with radium in cancer of the cervix had not justified its use in operable cases as a substitute for radical operation. Personal results of the radium treatment compared with those of the Memorial Hospital led to the conclusion that success depended largely on equipment and method of application not possessed by the users of moderate quantities of radium. There was a possibility that the view of operators would be changed by the future development of technique in radium application. For the present, however, operation was the treatment by choice by those to whom the highly developed radium therapy was not available.

An Analysis of the Failures in Radium Treatment of Cervical Cancer.—Dr. FREDERICK J. TAUSSIG of St. Louis stated that radium treatment of uterine cancer should be kept in the hands of the gynecologist rather than the roentgenologist, but such a gynecologist should seek preliminary training in the use of radium and must have continued opportunity for observation and treatment of cancer cases in order to reduce mistakes to a minimum. Good permanent results could be obtained in a certain proportion of cervical cancers with amounts of radium not exceeding 100-150 mgs. of the element, though the use of large amounts in the form of emanation would doubtless decrease complications and increase the number of cures to some degree. If possible, all necessary treatment should be given within the first 6-8 week period before sclerosis had set in and rendered the cancer less accessible and the normal tissues more susceptible to injury. Tumor filtration or light metal filtration together with intracervical application did most good and least damage; 2500-3500 mgs. were usually enough to give results in the favorable cases. In the absence of the Bailey bomb and large amounts of emanation, well directed and prolonged *x*-ray from 6-8 portals would usually affect the parametrial and glandular involvements. Prolonged necrosis and fistulas were due to repeated treatments, to vaginal applications and to heavy gamma radiation or to a combination of the three. Rectovaginal fistulas were more frequent and vesicovaginal fistulas less frequent after radium treatment. Operation was to be preferred in all operable cases under 35 years and in the early operable cases beyond this age. Radium was to be recommended wherever obesity, lung, heart or kidney lesions made operation difficult or dangerous, and in advanced operable, border-line, and inoperable cases but not in the advanced inoperable group with cachexia. The advanced inoperable cases had better be treated with acetone, since radium increased the tendency to fistulas and pain in most instances. These views are based on an experience extending over two and a half years in the treatment of 86 cases of cervical and vaginal cancer and 6 cases of vulvar cancer, in which radium or a combination of radium with operation was employed.

Lutein Cysts Accompanying Hydatiform Mole.—Dr. W. A. COVENTRY of Duluth, Minnesota, said that the cases which he reported presented several very interesting features: (1) The appearance of the ovarian tumors; in one case appeared with the mole (in fact, clouding somewhat the history of the mole) and in the other case seemed to arise and started to grow rapidly after the mole had been removed. (2) The gross and microscopical appearances of these cysts were in marked contrast to those of the ordinary type of ovarian cyst. (3) These multiple lutein cysts were beyond a doubt different from those normally appearing during pregnancy. (4) These lutein cysts undoubtedly accompanied only the formation of chorioepithelioma and mole and were probably not to be found in any associated condition. There were many references in the literature as to the occurrence of cysts of the ovaries accompanying pregnancy, mole, or chorioma, but he was sure that many of these references were only to small cysts, which disappeared spontaneously after expulsion of the mole or the fetus, as the case might be. From the appearance of such large cysts he was sure this was an uncommon condition. As regards prognosis and treatment, Eden and Lockyear asserted that some of these cysts receded following the expulsion of the mole, and some such cases had been recorded by Russell, Andrews and Albert, but this literature was not available. Findley commented that occasionally cystic ovaries became greatly reduced in size following delivery of the mole, and reported in the 58 cases collected by him that in only four was there any retrogressive change following the expulsion of the mole. Still, he did not specifically state that these were large lutein cysts such as described in this condition. In view of the fact that the literature in the large majority of cases connected this condition with the presence of chorioepithelioma, and also in view of the fact that the condition was undoubtedly a retrograde metamorphosis from the normal cystic conditions found in the ovary, he believed that we were perfectly justified in not waiting for the recession of these tumors, but that we should operate and remove them when found. The small cystic tumors of the ovaries, accompanying mole, he would be inclined to keep under observation. Whether a hysterectomy should be done at the same time as the removal of the tumors was an open question in the speaker's opinion.

A New Method of Covering Raw Surfaces Upon the Uterus.—Dr. GEORGE GELLHORN of St. Louis, Mo., stated that the practitioner started to do a Gilliam operation or one of its numerous modifications or substitutes in a case of fixed retroflection. The adhesions that held the uterus glued to depth of the cul-de-sac or the rectum were broken up, the round ligaments were shortened and the uterus was now lying in a more normal position, but with a more or less extensive area of denudation on its fundus which invited the speedy formation of new adhesions. The difficulty was easily solved by a procedure the various steps of which were given by the author in the following language: "The fundus is grasped by a vulsellum and pulled backward and upward in the direction of the promontory. The reflection of the bladder peritoneum upon the cervix, which now becomes plainly visible, is incised transversely as in a hysterectomy, and pushed off from the uterus. If this blunt dissection with the finger is gentle enough and does not extend into the broad ligaments, the bleeding is usually insignificant and is quickly checked by the pressure of a sponge. The uterus is then tilted forward, the bladder peritoneum is pulled over the uterus and stitched to the posterior aspect of the fundus, where an intact peritoneal surface presents itself. In small uteri, the bladder peritoneum may be fastened as far back as the insertion of the sacrouterine ligaments, if necessary. After the first or second turn of this continuous catgut stitch the vulsellum is removed and the stitching is continued until the entire fundus with its denuded area has disappeared beneath its new peritoneal covering. By using an inverting stitch, even the catgut knots become visible. The newly formed covering consists only of the bladder peritoneum which, in many cases, is so thin and transparent that the raw uterine surface and even the vulsellum holes may be distinguished." The method just outlined not only supplied the raw fundus with a new serous coat, but it also safeguarded a normal position and mobility of the uterus, and the late results had remained most satisfactory. It was, however, not to be relied upon exclusively in a case of fixed retroflexion. In such a case the order of the operative steps was, *first*, loosening of the bladder peritoneum as described above; *second*, shortening of the round ligaments; *third*, fastening of the bladder peritoneum to the back of the uterus beyond the area of denudation. He anticipated two pertinent questions. Was the function of the bladder disturbed after this procedure, and what happened to the bladder in a subsequent pregnancy? In the six or seven years that he employed the method, he had never observed an instance of vesical disturbance other than those that might follow any laparotomy.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON SURGERY.

Stated Meeting, Held March 5, 1920.

DR. SEWARD ERDMAN IN THE CHAIR.

Recurrent Dislocation of the Shoulder. Operative Results.—(4 cases.)—Dr. JAMES N. WORCESTER presented these cases.

CASE I.—This man, 35 years of age, had dislocated his left shoulder, on the Mexican border in 1917, by quite severe trauma. The arm was never immobilized but carried in a sling for two weeks. Ten days after this he sustained a second dislocation, which was reduced and treated as the first. Following this there were repeated recurrences up to forty or fifty times, caused by the slightest motions, as slipping off a coat. He was totally incapacitated for work. A brace was tried for preventing abduction without success. The first two reductions were rather difficult; the following ones were easy with the Kocher method. Physical examination showed a typical subcoracoid dislocation. Operation was performed on October 3, 1919, at the Clinic for Functional Re-Education. On the inferior and unsupported aspect of the capsule of the joint was a definite defect, triangular in shape, the base of the triangle being the line of attachment of the capsule to the margin of the humeral head and being about three-quarters of an inch in length. The longitudinal tear extended almost to the margin of the glenoid cavity, gradually diminishing in width. The anterior margin of the defect was quite sharply defined, while the posterior was much thickened and was formed by the adherence of the turned back triangular portion of the capsule. During operation by simple abduction of the arm a dislocation was easily produced. The operative procedure was as follows: A four inch incision beginning at the coracoid process running downward and slightly outward was made, the sulcus between the deltoid and pectoralis major found, and the two muscles separated in the axis of their fibers. This exposed the tendinous insertion of the subscapularis, which was divided transversely as was also the insertion of the pectoralis major for a distance of an inch. With deep retraction the inferior surface of the joint capsule was exposed. Considerable difficulty was found in overlapping the two edges of the defect in the position of abduction and external rotation which gave the best exposure. The outer three-quarter inch of the posterior margin of the defect were sutured to the periosteum along the rim of the humeral head and the remainder of the rent in the capsule was closed by means of mattress sutures with the arm in internal rotation and partial abduction. The subscapularis and pectoralis major were resutured with mattress sutures of chromic gut. The deltoid and pectoralis were approximated with plain gut, and the skin closed with silk worm and silk. There was no drainage. The arm was approximated to the chest with a Velpeau bandage. The wound healed by primary union. The arm was kept in adduction and internal rotation for twenty-one days. Following this active motion was started, limiting external rotation until 35 days when active and passive motion and massage were started. At the start abduction and external rotation were markedly limited but at present the limitation comprised only a few degrees. There had been no recurrence. He rather encouraged a slow stretching. There was still some doubt as to the man's ability to stand extreme muscular effort.

CASE II.—This patient, 32 years of age, Dr. Worcester said had first dislocated his shoulder by a fall aboard a transport in June, 1918. The dislocation was reduced but not immobilized. It recurred shortly after and had since been out thirty to forty times, gradually occurring more and more easily. At operation, on October 9, 1919, no defect could be found in the capsule at any point. The inferior portion of the capsule was very much elongated, so that the head could be slipped into the dislocated position with great ease during the operation. No other anatomical abnormality was found. The inferior portion of the capsule was opened transversely, parallel to the humeral margin and about one inch distal to the humeral margin, the incision being about two inches in length. The cut inner edge was then sutured underneath the outer flap to the margin of the humeral head by mattress sutures of chromic gut and the free edge of the outer flap was tacked down with chromic gut. The muscles and skin were sutured as in other cases. The wound healed by primary union. Immobilization was carried out as in the preceding case. On the first day after the Velpeau bandage was removed the patient fell down a subway steps receiving multiple contusions, but did not dislocate the shoulder though he struck it. Abduction and external rotation were moderately limited following removal of bandages but had rapidly returned to almost normal with exercise and mechanotherapy. He was doing fairly hard work as a farmer.

CASE III.—This patient, 25 years of age, first dislocated his shoulder in January, 1918, by a fall. No retentive dressing was applied, and a few months later it was dislocated again. Since then dislocation had recurred about nine times. In August of the same year his left shoulder was dislocated by a fall from a platform about four feet high, and this had also recurred about eight times. On several occasions both shoulders had been out simultaneously. He was admitted to the Second Surgical Division of Bellevue Hospital, and operated upon on June 17, 1919. On reflexing the subscapularis tendon and exposing the inferior aspect of the capsule, a triangular defect was found with the base of the triangle along the humeral attachment. The long axis of the tear ran toward the glenoid margin for a distance of about two inches, gradually diminishing in width. The anterior margin was sharp and well defined while the posterior was thick and apparently doubled back. A slight amount of clear fluid was present. A small fragment of cartilage escaped when the joint was opened. The inferior portion of the capsule was definitely increased in length. The humeral head did not seem to escape through this rent as the dislocation could be reproduced on account of the laxity of the capsule. A similar exposure was made as in the other cases. No attempt was made to resuture the capsule to the humeral margin as, owing to the laxity of the capsule, it was possible to overlap the posterior margin of the tear over the anterior for a distance of three-quarters of an inch along the whole length of the capsule, forming a distinct band or ligament. This definitely shortened the capsule without limiting abduction unduly. A Pagenstecher suture was used in this overlapping and the free edge was tacked down with chromic gut. The subscapularis was resutured with chromic gut and also the pectoralis major. The deltoid and pectoralis major were approximated with plain gut, and the skin with silk worm and silk. The arm was approximated to the side with a Velpeau bandage. The wound healed by primary union. The arm was kept in abduction and internal rotation for fifteen days, and abduction prevented for fifteen days more, when active and passive motion were started with caution. There was very slight limitation of any motions. The patient returned to the hospital on October 22, 1919, for operation on his left shoulder, which was done at the Clinical Congress of Surgeons. There was a distinct separation of the capsule from its humeral attachments on its inferior aspect, about 1½ inches in length, filled with a thin fibrous tissue. The gap between the torn edge of the capsule and the rim of the humerus was almost an inch in length, making the capsule on its inferior aspect markedly elongated. The torn edge of the capsule was freshened and sutured to the periosteum of the humeral margin with mattress sutures of chromic gut passed through the capsule about one-half inch from its edge and the free edge was sutured to the periosteum at the base of the lesser tuberosity. The wound healed by primary union. The arm was kept in adduction and internal rotation for twenty-one days. There was very slight limitation of motion and the patient was doing heavy work, which he stated would have dislocated his shoulders before the operation. Three of these cases showed a condition different from that described by the majority of writers on the subject in that the separation of the capsule from its bony attachments was at the margin of the humeral head rather than at the glenoid margin. The simple laxity of the capsule described in Case II had been

reported frequently, but if we were to regard all dislocations as sprain fractures, which he thought we should, it might be that he had overlooked a similar condition to that found in the left shoulder of the last case and that the separation had been healed with firm fibrous tissue which had stretched. This type of case was not particularly common when one considered the number of shoulder dislocations. He thought an exception to the theory of early mobilization of joint injuries might be made in these dislocations, and that a position of internal rotation and adduction for 18 to 29 days might give a chance for the torn capsule to heal in a fairly normal relation and prevent recurrence.

Dr. GEORGE H. SEMKEN said he felt that Dr. Worcester should be congratulated on having obtained such brilliant results in all three cases. He recalled two cases, one of which showed a laceration of the capsule. If the dislocation was the result of trauma and there was laceration of the capsule the method of procedure indicated was to repair the capsule. If there was no such obvious trauma the question arose as to what produced the condition. In repairing the capsule he had used a fascial graft such as Ferguson adopted in operating on keloid. This skin graft contracted and was converted into a fibrous cord which strengthened the flaccid capsule. One could make use of this procedure to reinforce tissues still remaining. It was an easy matter to expose the shoulder joint through the inferior and anterior aspect, which gave access to the triceps fossa.

Dr. ARMSTRONG asked Dr. Worcester if he had had any trouble from injury to the nerves coming from the brachial plexus. He knew of one instance in which there was a very troublesome complication due to injury to a nerve.

Dr. ERDMAN said that Dr. Worcester's cases suggested the question whether mobilization was applicable to all points and whether there were not certain types of operation in which early motion was contra-indicated.

Dr. WORCESTER, in closing, said that in all these cases there had been a definite defect or a definite laxity of the capsule which would be repaired by this operation. His idea was not to reef so tightly as to limit abduction and rotation. He had never tried to use a fascial graft for he feared it would contract too much and one would then get marked limitation of abduction. Another point was that the incision used perfectly avoided the vessels, going a little to the inside; then they could be retracted, and there was no hemorrhage. If there was hemorrhage it would make operation difficult, because one was working in a deep cavity. He did not think the incision through the deltoid gave as free access to the anterior and superior parts of the joint as the one he had used. As to Dr. Erdman's question concerning mobilization, he felt quite strongly that every dislocation was a sprain fracture, the capsule being torn from the margin. Certainly in the shoulder the way that capsule would heal most normally was when the inferior portion was without tension and that was by abduction and internal rotation; hence he felt that the shoulder should be immobilized, as in these cases, from 18 to 20 days. Then a torn capsule would heal in a fairly normal position, and there would be fewer recurrences than if the arm were mobilized immediately.

Injection of Gasserian Ganglion for Trifacial Neuralgia.—Dr. EDWARD W. PETERSON reported this case. He stated that the patient had suffered for eight years with intractable trifacial neuralgia. He had had to give up work and was under the influence of opiates most of the time. His condition was such that relatives thought his mind was affected. An injection of ½ c.c. of 2 per cent. novocaine, followed by 1 c.c. of 95 per cent. alcohol resulted in perfect anesthesia, so that the patient could not feel a cut or pin prick. Following this procedure he had not ordered morphine, and the man complained of a little pain, so a second injection was given, but he was inclined to think the man complained of the pain because he desired an opiate. Following the second injection there was dilatation of the pupil. The anesthesia and analgesia were perfectly satisfactory. The man was able to return to work in a few weeks and had gained from 15 to 20 pounds. His general condition was satisfactory. As to the technique of making the injections, he had first tried it out on the cadaver. One could use the Hartel, Schlosser, or Offenhaus methods. The puncture was made opposite the second upper molar, passing a spinal anesthesia needle in until the infratemporal plane was reached, and then going downward and inward until one entered the foramen ovale. One could tell when the foramen was reached because there was no sense of resistance. One should then pass the needle about 1½ cm. further, and make the injection very slowly. If the needle had reached the proper place the anesthesia would be immediate, one would have injected all three branches of the trifacial nerve, and anesthesia would result in the area supplied by the branches of this nerve. It might be necessary to make the injections from one to three or four times in order to get complete analgesia. Dr. Peterson said he had treated about twenty cases in this way. The method was 100 per cent. efficient if the technique was properly carried out; if the results were not good it was the fault of the technique and not of the method. As the procedure was painful, it was better to do it under gas anesthesia. As the novocaine produced immediate anesthesia the injection of the alcohol was practically painless. The needle should be left in place after injecting the novocaine, and the alcohol injected before removing it. Some of these patients had been taking morphine and might claim that they had pain when such was not the case. As a rule one injection into the ganglion sufficed; if it did not it could be repeated.

Dr. ROBERT T. MORRIS asked Dr. Peterson whether in these cases he knew anything about the possibilities of recurrence, and how long after this procedure the patients had had immunity from neuralgia. Neuralgia was a symptom for so many conditions that it was merely a sort of expression like a cough indicating trouble somewhere else. The neurologist, with his attention centered on neuralgia as a diagnostic entity, was very apt to overlook other conditions. A study of peripheral irritation and of focal infection was required in almost any case of neuralgia. As a rule the ground was only partly covered by the diagnostician. The length of immunity period after an operation like that Dr. Peterson had described would depend upon the kind of trouble that had expressed itself in this symptom of neuralgia.

Dr. PETERSON, in closing, said the average time these patients were free from neuralgia was about one year. The shortest time in his series was about six months, and the longest time where the injection had to be repeated was about three years. He thought the average time was from twelve to fifteen months. As to the cause, if one could find any of the causes that Dr. Morris had mentioned the case was not suitable for injection. These were the "essential" neuralgias. If there was sinus trouble, tooth infection, eyestrain, syphilis, tumor, or any other definite cause to explain the neuralgia, it was not a suitable case for injection. As to the possibility of corneal ulceration, one had to protect the eyes just as in a Gasserian ganglion operation. The anesthesia was such that the possibility of corneal ulceration had to be taken into consideration. The injection method was only palliative, or occasionally curative. According to Sicard quite a number of cases had been relieved permanently by this method. He had one patient, sent to him by Dr. John Erdman, whom he had injected three times. The first injection gave relief for fifteen months, the second for twenty-five months, and the third injection was given last May, nearly one year ago; the patient was still free from neuralgia.

Willem's Treatment Following Operation for Internal Semilunar Cartilage.—Dr. BURTON JAMES LEE reported this case for the purpose of bringing up the subject of Willem's treatment by active joint mobilization following joint operations as it was employed in the war zone, where immediate mobilization without splints had been used with marked success. The patient who illustrated this principle entered the New York Hospital early in February. He was 24 years of age and had had symptoms for eleven months. On several occasions the right knee joint had locked, with pains over the internal semilunar cartilage and a subsequent

effusion into the joint. The man had been incapacitated for work for almost a year. The operation was done through a small transverse incision through which the semilunar cartilage could easily be seen and readily delivered. The synovial membrane was sutured separately with catgut, the ligaments with chromic gut, and the skin with silk. Active mobilization was instituted immediately following the operation, and was continued at frequent regular intervals. No passive motion was allowed. The point made by Willems was that passive motion traumatizes while active motion was nontraumatizing. Another point made by Willems was that most dressings applied to the knee were large and bulky, and interfered with immediate mobilization. Very limited dressings were used after the third day. The case also illustrated the degree of flexion that could be obtained by immediate mobilization. Seven days after the operation the man was walking about the ward with the aid of a crutch. Dr. Lee said he reported the case because he felt that we should make use of the lessons learned during the war in civil surgery. This principle had been used abroad very successfully, giving good results even in suppurating joints and acute septic knees if there was not a massive fracture with displacement. The patient was encouraged to move the joint from the first. In the war hospitals he had seen at one time as many as six or eight patients walking about the ward with their knee joints exuding pus and without pain. The patient presented this evening had been operated upon one month ago. There was still a certain amount of fluid in the joint which he attributed to the fact that the patient had not worn a compressive bandage.

Dr. CLARENCE A. MCWILLIAMS said that Willems did not use splints. The patient, as soon as he came out of the anesthetic, was immediately made actively to use the joint, and to keep up moving it every two hours of the day and night until the joint had perfect function. The movements were all active, never passive, as passive motion caused pain and injury to the joint which took time to repair. He had recently seen two cases of semilunar fracture, one of which was caused by a bullet wound, in which there was effusion into the joint. This sometimes happened, and with the old form of treatment it took from three to five or six weeks to get over the effusion. Willems, in such cases, immediately aspirated the joint, and as soon as the fluid was removed the patient moved the joint. It was frequently the fluid in the joint, and not inflammation, that prevented motion. The fluid might reaccumulate and the joint might have to be aspirated four or five times, but if active motion was begun at the time of the first aspiration the patient lost no time from work and was cured. That was true also of chronic synovitis. The method was, as Dr. Lee said, particularly applicable in septic joint. Willems had published a report of 100 cases, in which there was not a single death. In one hospital of the A. E. F. there were 80 cases of septic joints; there were 8 deaths among the 80 cases, and something like five or six amputations. He had seen the Willems method employed in other hospitals in France, and the results of the treatment were infinitely better than by any other means. As soon as the patient came out of the anesthetic he was made to actively move the joint, lifting it a little from the bed. It was surprising how little pain movement caused. It was likewise surprising how much drainage was obtained by the contraction of the joint. These patients walked about the ward without temperature or constitutional symptoms, such as one expected to see in septic joints. All fractures in which there was no dislocation of the fragments to be produced by the movement should be treated by this same method, and there were comparatively few fractures in which there would be a dislocation of the fragments because of motion.

Dr. JOHN J. MOORHEAD asked why Dr. Lee had used the transverse incision. He said the incision he used when he was not sure whether or not he was dealing with a semilunar dislocation was the patella-split, the one advised by Sir Robert Jones. He could verify the usefulness of early mobilization in all sorts of joint injuries. He had learned of a modification of the method from English surgeons, namely, in sensitive individuals who would not move the joint a start was made by placing a small pillow under the knee and gradually raising it as the day progressed. Then at night the pillow was depressed. In this way the patient would retain more confidence than if he was forced to bend the joint against his will.

Dr. LEE, in closing, said he thought with the transverse incision one gained easier access to the cartilage. He had used the vertical incision and thought it not so good. Concerning the general principle involved in Willem's treatment, it was very revolutionary, particularly in septic joints. One word of warning should be given, however, for one heard all sorts of opinions as to the efficiency of this method of treatment. What really happened was that when there was great activity in the American army abroad green surgeons were assigned to duty who did not apply the treatment well. Dr. McWilliams had followed out the treatment carefully. Dr. Lee stated that after the armistice he had visited all the American hospitals, and had found that the treatment had always been immobilization in the cases which had come to amputation or had resulted fatally. In bad septic knee joints nothing would drain the joint except active motion.

The Use of Picric Acid in Preparation of the Skin.—Dr. CHARLES E. FARR read this paper, in which he stated that picric acid had been used in the preparation of the skin for operation at the New York Hospital for about two years. The properties which particularly commended it for this purpose were the absence of irritation, its quality of penetration, and its bactericidal power. Picric acid in 5 per cent. alcoholic solution could be applied with impunity except to the conjunctiva. Care must be taken not to tan the skin too much or blebs might form and infection ensue. It was true that where infection or impetigo existed irritating chemicals, such as iodine, must be used with exceeding care in connection with picric acid. In order to determine the effect of picric acid on the peritoneum, experiments had been carried out on guinea pigs, applying acids of varying strengths to the peritoneum. There seemed to be no ill effects except that the animals were slightly shocked by the peritoneal irritation. Laparotomies were performed on these guinea pigs after several weeks, and no adhesions were found. The intestines at the time of applying the picric acid were subjected to a good deal of handling, and in spite of this the animals made a good recovery, and later, at post mortem examination, nothing abnormal was found. They had concluded that in guinea pigs picric acid did not cause adhesions. There was no systemic or toxic reaction following its use, even when large areas of the skin were covered. It was not to be expected that any germicidal preparation would penetrate to all the layers of the skin, but the penetrating power of picric acid was about that of iodine. It had decalcifying qualities and because of these it might extend further and last longer than iodine. It seemed possible that picric acid acted not so much through its germicidal power as through its mechanical properties; it enmeshed, held, and sealed germs in the skin. Practically all the picric acid applied remained on or in the skin. That was the great objection to its use; it was exceedingly difficult to remove. Following the use of picric acid in the New York Hospital there had been a marked improvement in the appendix cases. Formerly the bad end results in chronic appendix operations had run as high as 28 per cent. Later they dropped to 20 per cent. Then they began using picric acid and the bad results fell to 11 per cent. It was noticed that the number of patients complaining of bad end results and of pain in the neighborhood of the incision, presumably due to adhesions, markedly diminished. The technique in the appendix cases was exactly the same with the exception of the use of picric acid. From the standpoint of clinical results picric acid compared favorably with iodine for the preparation of the skin, though no method could be accepted as satisfactory unless laboratory investigation showed that it met bacteriological requirements.

Dr. GEORGE WHITING WHEELER said that when Dr. Farr began these studies he had been asked to provide him with laboratory data as to the relative efficiency of picric acid and various antiseptics, especially iodine. It had been customary to accept the phenol coefficient described by Rideal and Walker, or by the United

States Public Health Service as the test of bactericidal power. By this test it was found that a 5 per cent. alcoholic solution of picric acid had a phenol coefficient of 0.3, giving it only one-third the bactericidal power of phenol. In the presence of organic material this coefficient was still less, being below 0.2. Seven per cent. iodine had a phenol coefficient of 15, therefore its bactericidal power is about 45 times that of 5 per cent. picric acid. These methods, however, did not take into account the fact that picric acid was to be used on the skin. To make the test under conditions more analogous to those of the skin, Elser's method, which gave an index of the penetrating and bactericidal power, was employed. With this test strikingly different results were reached than those obtained by the phenol coefficient test. This test consisted in making cultures of staphylococcus in agar-agar tubes. The tubes were inoculated and allowed to solidify, and then various disinfectants were added and their action observed in this resistant medium. After making these tests they concluded that the phenol coefficient alone was not very reliable, as an index of the practical value of any antiseptic to be used for skin sterilization. They then studied the question by the use of blood serum and body fluids, in order to approach still more closely to the conditions existing in the living tissues. In that way they decided that the practical value of picric acid lay not simply in its bactericidal power but rather in its penetrating power. In tests of this kind picric acid, so far as its penetrating power was concerned, was almost if not quite as efficient as iodine.

Acute Osteomyelitis; Experimental and Clinical Study.—Dr. FREDERIC W. BANCROFT gave a lantern slide demonstration showing the results of attempts to produce experimental osteomyelitis in animals. In certain of these experiments a cavity was made in the bone of the animal and staphylococcus introduced and the hole sealed up with bone wax. By this method they had succeeded in producing a hematogenous osteomyelitis. In some of the animals in which the staphylococcus was introduced an acute fulminating infection resulted, causing death in about four days. Post-mortem examination of these animals showed an extensive suppurative oseomyelitis, and abscesses were found in the kidneys. By modifying the conditions of the experiments a chronic osteomyelitis was produced. In considering the treatment of osteomyelitis Dr. Bancroft emphasized the importance of conserving the blood supply and of preserving as much as possible the integrity of the bone. Even in cases in which there was pus under the periosteum, a certain number of cases would get well without medullary drainage. Secondary sequestra sometimes developed and involved a joint. When this occurred the joint should be aspirated. When septicemia developed blood transfusion was one of the greatest aids in treatment.

Dr. REGINALD H. SAYRE exhibited a series of *x*-ray plates bearing on the paper, though in this instance the epiphysis was involved rather than the shaft of the bone. He said that the child came into the hospital with a very high temperature. The abscess was opened and the culture of the pus showed the *Streptococcus hemolyticus*. The *x*-ray of the femur, showing a large sequestrum, made him feel that perhaps he should do a resection. The child, after the abscess was drained, was doing well, so he waited and had successive *x*-rays taken, which showed the gradual disappearance of the foci, so the child was not operated upon. The last *x*-ray, taken in October, 1919, showed that the focus had apparently disappeared. The child was running about. The question in this case had been whether to scoop out the bone or follow a waiting policy, since some of these cases healed up of themselves, as shown by Dr. Bancroft, particularly in children. There was no question that early drainage in acute osteomyelitis was most essential, and it seemed to him that a good many physicians not connected with hospitals did not recognize the urgency of the need for immediate operation. They waited until the child was acutely septic, and it was too late to save him. With the influenza there had occurred a great many bone infections with subsequently secondary infections in other bones.

Dr. L. T. LE WALD asked how early Dr. Bancroft was able to obtain *x*-ray evidence of the existence of acute osteomyelitis. He was often asked to diagnose an acute osteomyelitis by radiographic examination, and ordinarily he could not do it early in the course of the disease.

Dr. BANCROFT, in closing, said they did not get pictures of the cases that died of acute fulminating osteomyelitis. He had found the *x*-ray of no help in the early stages. He did not think it showed anything for two weeks, not until there was death of the bone and subperiosteal involution.

Non-Rotation of the Colon and Its Relation to Appendix Pathology.—Dr. DUDLEY ROBERTS reported this case, which he illustrated by lantern slides. He stated that when the *x*-ray examination of this patient was made and showed the bismuth streaming into the iliac fossa, they thought they were dealing with an artificial fistula connecting the small with the large intestine, but on further study it proved to be a case of non-rotation of the colon, a condition which he found had not often been reported. Non-rotation of the colon was characterized by the ileum entering the cecum on the right side rather than on the left; the cecum faced the inner side of the body and that happened in all cases, no matter at what stage of rotation the case was left. In going through the literature he had found only 18 cases. In six of the 18 cases the operator had been unable to find the appendix in the normal location, and subsequently found that there was a non-rotation of the colon and the appendix was on the left side. This patient gave a rather interesting history of pain in the lower abdomen, somewhat to the left of the median line, and attacks of nausea and vomiting during a period of ten years, but his condition was never definitely recognized as related to the appendix. Dr. Roberts thought that failure of rotation of the colon was likely to be associated with a pathological condition of the appendix, though he could offer no explanation.

Dr. L. T. LEWALD said he had seen four other cases of non-rotation of the colon besides the one Dr. Roberts had reported. All were of about the same type, though there were several variations, most of which had been illustrated by Dr. Huntington in his work on the subject. The first slide which Dr. LeWald showed he said was of considerable interest, as it showed almost the duplicate of what Dr. Huntington had shown, namely, the relationship of the duodenum to the non-rotated colon, which might lead to serious error if the condition was not recognized. In one instance a radiologist reported a lesion about the duodenum, and advised operation. In this case no *x*-ray study had been made of the colon, but when finally the entire intestinal tract was studied the condition was recognized and no operation was performed. A second case of which *x*-ray plates were shown gave practically the same history, and in this instance also only the stomach had been examined by the roentgenologist. At operation an incision was made in the median line high up, and then by reaching over to the left side an attempt to deliver the appendix was made. This was impossible to do. No further operative procedure was carried out. He scarcely felt that there was justification for associating appendicitis with non-rotation of the colon. He had seen two cases associated with duodenal ulcer. In one of these Dr. Downes had not known that the condition of non-rotation existed and he had picked up a piece of the small intestine and nearly started to anastomose it with the stomach. Dr. LeWald said he had immediately suggested that it was a case of non-rotation of the colon; this was proven to be the case and an anterior gastro-enterostomy was done. In another case, the *x*-ray plates of which were shown, was not operated upon. The fourth case was one with pylorospasm and pyloric obstruction in a child 12 years of age, in which the *x*-ray showed non-rotation of the colon. So he felt that one could not say that non-rotation of the colon was associated especially with appendiceal disease. Dr. LeWald said he had mentioned in the article to which Dr. Roberts had referred that one might see a combination of non-rotation of the colon and transposition of the viscera, which would bring the appendix back on the right side. Such a case he believed had been reported in one of the South American journals.

Miscellany.

How Smallpox Was Fought at Milan.—Bordoni Uffreduzzi, director of the health office at Milan, describes in the *Annali d'Igiene* for February, 1920, xxx, 2 the recent stamping out of variola in that locality. The disease had appeared in 1896, 1901-4, 1911-2, and lastly in 1917, when it was diffused over much of Italy. It first appeared at Turin among war prisoners and in a short time 1,467 cases had been reported in several hundred foci. In 1918 the total number of victims had reached over 4,000, and in 1919 the total had advanced to 32,780. In Milan there was no case until 1918, and that year but two were reported, and in 1919 the total was but 75 in a population of over 700,000. It is therefore evident that an effective prophylaxis must have been in force. This goes back to 1902, when it was made compulsory to notify cases of varicella. There have been vaccination laws in Italy, making the act compulsory since 1892. These comprise revaccination after a stated interval. If left to the community not a third of the newborn children would receive the primary vaccination. Hence summons are issued to refractory patients and if need be repeated. The period of primary vaccination reaches through the first two years of life, while revaccination is intended to occur between the ages of eight and eleven years. There is a special provision to cover immigrants to the city. Not less than 80,000 individuals are vaccinated annually in Milan, but despite the large figure it is not claimed that the community as a whole is protected. But relative immunity is secured so that chain transmission is impossible. The number of nonimmunes and partly immunized cannot of course be computed and one can only compare Milan with other places, often of relatively small size, in which the laws have not been enforced with the same rigor. Thus in Bari in 1919 the number of cases reported was 2,687, and most of the victims were young children, as was always the case in Jenner's day. In Naples, which is about the size of Milan, the number of smallpox victims in 1919 was 2,066. The immunity of Milan is due to strict enforcement of the laws. In the twenty-four years of the Isolation Hospital not a single attendant or physician has contracted smallpox from the patients, vaccination having proved a full protection.

The First Case of Ainhum in Peru.—Drs. Soto and Raffo of Lima have reported this case in *El Siglo Medico* for May 8, 1920, lxvii, 3465. The patient entered the San Juan de Dios Hospital in that city in August last. He was a negro aged 29 and engaged in agriculture in Chincha. There was apparently no question as to the diagnosis and the patient affirmed that several other members of his immediate family suffered from the same malady. These were his mother, his mother's mother, and a cousin on the maternal side. The father and his people were intact. The patient had noticed his affection six years before. The author points out the countries in which ainhum is endemic. These comprise much of Africa where the negro is the usual victim, Madagascar, India, etc., and in the Western hemisphere Brazil. Rarely cases have been seen in the North American negro. The disease has been practically limited to the dark races and especially is the negro affected. It has been seen in Argentina, but the author mentions no other South American State, always of course excepting Brazil. On account of its prevalence on the African West Coast it might conceivably be smuggled into Eastern South America, but not the Pacific coast. It seems to have made its way into Polynesia, however, and in time may spread to countries thus far immune. The cause and mode of propagation are obscure. It is said to be due to local trophic causes, central trophic causes, parasites, etc., and at times, as in the present episode, has a familial or hereditary tendency. Castellani regards it as parasitic and the flea ox-chigger may possibly be the agent of transmission. Manson sees nothing more than a purely mechanical motivation beginning in petty wounds in men who go barefoot, these wounds leading to the development of a cicatricial process which amputates the toes. Division of the constricting bands interrupts the process.

Rabies Disappears from Poland. — One of the curious results of the war reported by the American Red Cross in Poland is the almost complete disappearance of rabies. Five years ago rabies was a very common disease in that country, presumably owing to the large number of wolves and semi-wild dogs. The Pasteur Institute in Warsaw, which was opened by Pasteur himself, and which was the second Pasteur Institute in the world, is said to have given more innoculations than any other institute. When the American Red Cross first visited it, however, to offer assistance, they found only one doctor and one patient. The building had been stripped by the Germans, but the lack of equipment was not taken very much to heart by the two occupants. "You see," explained the doctor, with a smile, "we don't have very many mad-dog cases now, because the Germans ate up all the dogs."

Early American Edition of Lavoisier's Chemistry.—Graham Lusk of New York and Jean Le Goff of Paris contribute an article on this subject in the *Gazette des hôpitaux* for May 1, 1920, xciii, 41. The edition in question does not seem to have been known to bibliographers, but a copy fell into the hands of Professor Lusk which is merely an American imprint of the fourth edition of Robert Kerr's English translation of the original French work. The date is 1799, and the publisher, Matthew Carey, Philadelphia. The original English edition was issued in 1790, and according to data found in the British Museum the fourth English edition bore, like the American issue, the date 1799. It is known that a fifth edition appeared in Edinburgh in 1802 and in New York in 1806, and up to the time of Dr. Lusk's find this edition passed as the first American. The original French edition came out in 1789 and, as already stated, the first English edition appeared one year later. The first Spanish edition appeared in 1798, the first Italian in 1791, the first Dutch in 1789 and the first German in 1792. Five English—seven including the two American editions—appeared in the space of sixteen years and four Dutch editions in twelve years. Three French editions are mentioned.—1790-1801.

TONSIL INFECTIONS.

BY S. R. SALZMAN, M.D., F.A.C.S.,

TOLEDO, OHIO.

SINCE Billings first emphasized the importance of focal infections, considerable literature has sprung up on this subject. Many physicians have been very enthusiastic concerning the results obtained by eradicating focal infections, while others are still lukewarm and at times skeptical. I feel, however, that too much importance cannot be attached to the tonsils as a source of infection. It is my conviction from careful observation of all patients that have come under my care during the past ten years that the tonsil is by far the most common source of chronic focal infection we have to deal with, and that this infection is far more common and widespread than most of us are apt to conceive. A few moments' thought will readily convince one that this is but natural.

The tonsils are infected in many cases early in childhood. Everyone doing general practice has seen cases of tonsillitis in very young children, even in infants of one to two years old. These tonsils may be repeatedly infected, so that throughout childhood a number of such attacks occur, and the glands in the neck become enlarged, showing that the infection has spread past the tonsils into the lymph stream.

From the anatomical structure of the tonsils we can readily see that once the deeper parts are infected, the tonsil can never completely empty itself of the infected material; but, on the other hand, as shown by Rosenow, the gradatibns in oxygen pressure within the tonsil make for excellent culture material.

The fact that when the child reaches the age of fourteen or fifteen the attacks of acute tonsillitis subside, often mislead us into the belief that the infection has subsided. It is at this time, however, that the systemic effects become manifest, slowly, insidiously, but nevertheless, surely.

The majority of otolaryngologists to whom I have put the question regarding the function of the tonsil agree that the tonsil normally should atrophy after adolescence. If this be true, we are justified, I believe, in considering practically every tonsil in the adult a pathological structure, and that this tonsil tissue was prevented from undergoing physiological atrophy because of the residual infection within it. If this be true, the possibilities of injury to the body by this focus of infection become of greater importance than we have heretofore realized. It is easy to go one step further and realize that it is entirely possible (and often the actual state of affairs) that the tonsil is the primary source of infection from which many other foci of chronic infection may be developed (excluding, of course, dental infections).

Deaver[1] states that in many cases of gall-bladder infection he has been able to trace the infection back to the appendix. I believe that we can go still further back and trace the infection of the appendix to the tonsil. That the infection of the appendix, gall-bladder, and even ulcer of the stomach and duodenum are hematogenous in origin, and that the tonsil is often the source of infection, has been conclusively shown by Rosenow. While this fact has been recognized in a general way, its specific application to the cases of appendicitis and gall-bladder infection constantly coming under our observation is usually overlooked.

In a paper read before the Toledo Academy of Medicine, February, 1914, I made the following statement: "In order that more definite information may be obtained, it is necessary that the tonsillar history of every case of appendicitis going to operation should be specifically noted. Only in this way can we hope to determine whether hematogenous infection of the appendix does occur and its frequency."

I have paid particular attention to this history. I can say definitely that I cannot recall a single instance in which the tonsils were not infected, or had not been the cause of so much trouble that they had been removed within a short time prior to the attack of appendicitis. This holds true, though not so uniformly, for gall-bladder infections also.

In gall-bladder infection, lymphatic infection and infection upward from the duodenum undoubtedly occur. But here again we must consider the possibility of it being secondary to an infective gastritis[2], which may result from the infective material being swallowed as it is forced out of the tonsil crypts.

But little need be said at this time upon the subject of rheumatic, arthritic, and endocardial infection. This is universally recognized. The fact that I am anxious to bring out is that a large proportion of the patients that ordinarily visit our offices are suffering either directly from a tonsillar infection, or it is an associated factor in the patient's debility, and that the economical importance of this subject has been largely underrated.

The number and variety of conditions which in

my experience have been due to tonsillar infections are very large and it might be worth while to mention briefly a few of these varieties. In the young child it is a common thing to be told by the mother that the child does not eat. These children not only are poor eaters, but they are very particular in the choice of foods. They eat only foods that tickle their palate, sweets. It is very difficult to get them to eat vegetables or even cereals, unless well sweetened. They have not a healthy appetite. The majority of them also complain of "belly ache" in the morning upon arising and will not eat any breakfast. They feel better along about eleven or twelve o'clock, and will partake of a little food at this time. Attacks of acute pain in the abdomen with some elevation of temperature and vomiting are not uncommon, often not associated with painful sore throat. Examination of the tonsil, however, will invariably show a number of white, cheesy deposits in the crypts of the gland.

Typical acute appendicitis will occasionally be seen in these children after a number of the attacks previously described have occurred. Removal of the tonsils brings about a remarkable change. The mother will tell the physician that it is almost impossible to give the child enough to eat, and that she has no further trouble in feeding vegetables. This is a rather common picture and not overdrawn. Many attacks of fever (febricula?) with no symptoms may be accounted for if the tonsils are examined in every case.

Mild infection with a moderate degree of anemia is not uncommon. This anemia may or may not be of the chlorotic type. One example may illustrate the type very well.

CASE I.—Miss J. H., age twenty-three, came to the office March 5, 1910. Complaint: feels tired, noticed some slight loss in weight, appetite has been poor, cannot do her work as saleslady as efficiently as previously. Menstruation scanty, but regular; bowels constipated. Has almost daily headaches. Physical examination revealed nothing abnormal anywhere, except that the tonsils were reddened and a slight amount of pus could be squeezed out from the crypts. She told me that so far as she could remember she had never had an attack of tonsillitis. Blood examination: Hb. 65 per cent., red cells 4,000,000, white cells 8,000.

After appropriate treatment for her anemia and attention to her bowels, she was soon feeling well again, weight and strength increased, and within three weeks she thought herself perfectly well. At the end of two weeks more the treatment was discontinued. She returned in three weeks feeling as bad as before; Hb. had again dropped to 70 per cent. Another course of iron and arsenic brought results similar to the first course, with a third relapse shortly after treatment was stopped. Examination of the tonsils again revealed considerable pus in both tonsils. Removal of the tonsil was then advised, and this was done by Dr. A. L. Steinfeld. Improvement began almost immediately, and without any further medication, within one month the patient thought she felt as well as ever; her Hb. was 85 plus, her color was good. This patient has remained well up to this time, a period of five years. This type of condition is very common.

Another very common type is one in which the chief complaint is of constant fatigue and lassitude. The patient gets up tired in the morning, feels moderately well along about mid-day, and again is fatigued by three or four o'clock in the afternoon. Headaches are common. Her social duties are too much for her, yet she cannot say that she is sick. A physical examination may show nothing whatsoever wrong, except the presence of infection within the tonsil, and at times I have noted a low systolic blood pressure of less than 110 mm. Hg. Removal of the tonsils in these cases is immediately followed by relief from the sense of fatigue. Often this result is brought about within twenty-four hours. The improvement may be in other ways also, as one patient remarked to me, "For years I have been mean and irritable. I have felt like biting people's heads off. Why, I feel like a different individual now."

Somewhere in my student days it was impressed upon my mind that the sense of exhaustion or fatigue upon arising is significant of neurasthenia. However, I am becoming more and more convinced that it is a characteristic symptom of infection, and particularly of tonsillar infection, because this is the most common infection in the body. A careful consideration of this class of patients will, I believe, still further lessen the number of cases that can be put into the class of neurasthenia.

Another type is one showing abnormal findings in the urine. These can be grouped under three different headings: (1) Cases of simple albuminuria. (2) Cases showing casts, slight amount of blood, with or without albumin. (3) Cases showing unusually large amount of blood, even to the passing of what appears to be pure blood.

The first type is not at all uncommon, and it is possible that if orthostatic or adolescent albuminuria were studied in large groups, as reported by Roger I. Lee[1] of Harvard University, and particular attention were paid to the condition of the tonsils, some association between the tonsillar infection and this albuminuria might be found. Lee found albuminuria present in 5 per cent. of every group of students examined. It is safe to say that the percentage of tonsil infections in these students is greater than 5. I have had five or six such cases all of whom came to me because they had been rejected for life insurance because of albumin in the urine. In all these cases removal of the infected tonsils cleared up the albuminuria.

It might be of some interest to try to account for the appearance of albumin in the urine in the students, as reported by Lee, after track work and exercise. The following experience is rather illuminating:

CASE II.—M. E., following scarlet fever, developed cervical adenitis and had daily fluctuations in temperature from 99.2° in the morning to 102.5° in the afternoon. She was a plump, healthy, active little girl of seven, an only child and rather spoiled, and as she felt comparatively well, despite her temperature, the mother was unable to keep her quiet. She bounced around in bed, played rather hard, and even got out of bed. It occurred to me that as she was not sick, if I could keep the little patient quiet, the temperature would subside. That her extreme activity probably resulted in massage of toxins from the glands into the circulation, resulting in her afternoon rise in temperature. As it was impossible to keep her quiet by ordinary methods, on account of the temperament of the child, I resorted to the use of sedatives. Sufficient chloral hydrate was given through the rectum to keep her somnolent for forty-eight hours. The first afternoon temperature was 99.8°, the second afternoon it was 99.4°, and never went higher. I had been watching her urine because of the possibility of nephritis; a trace of albumin was present during the time of her

high temperature and physical activity, but disappeared promptly with the drop in temperature and the complete physical rest.

This and a similar experience with a case of cervical adenitis following tonsillitis may throw some light on the effect of physical exertion on the presence of albumin in the urine, when a focus of infection, such as infected tonsils, is present in the body. A study of the cases reported by Lee from this standpoint may reveal some association between the tonsils and the albuminuria.

The second type is most common in the fourth decade of life. These patients occasionally complain of debility, lack of energy, often have a slight headache, suffer from vague and fleeting pains in various parts of the body, especially in damp or wet weather. An examination of the urine shows a considerable number of casts, chiefly hyaline, from 6 to 10 blood cells to a field, and occasionally a trace of albumin. The urinary findings vary from time to time; occasionally the urine being normal, at other times these findings are present. Not infrequently a history of a slight sore throat and stiffness in the muscles of the neck will precede the presence of these findings in the urine. Functional tests of the kidney show no loss in function.

The third type is less common, but very important.

I have had three examples of this type.

CASE III.—The first, S. S., eighteen years old, came into the office in March, 1916. Complaint: for four or five days had been passing what he considered pure blood in the urine. Urine passed at the office was of a bright red color, resembling thin, fluid blood. No pain was complained of, no backache. Has had repeated attacks of tonsillitis since childhood, otherwise considered himself well. The tonsils were very large—in fact, large enough to produce the thick voice associated with very large tonsils. Physical examination otherwise showed nothing unusual. The urine under the microscope resembled a drop of blood. The patient was referred to Dr. F. A. Douglass, who made a cystoscopic examination, and reported him back as suffering from "essential hematuria." The bleeding persisted for one week, at the end of which time an attack of tonsillitis again occurred. The patient was then advised to have the tonsils removed; after this attack subsided. Dr. A. L. Steinfeld removed the tonsils. Within one week no signs of blood could be seen in the urine with the naked eye, within another week the microscopic specimen was clear. The following summer the patient returned, stating that that morning he had again voided what appeared to be pure blood, and careful inquiry revealed the fact that he had eaten an unusually large quantity of rhubarb. The condition cleared up on advising him to eliminate this vegetable from his diet. Up to a year ago, when I last saw the patient, there had been no recurrence of the bleeding. The susceptibility of this kidney to hemorrhage from irritation by the oxalate crystals possibly points to some actual damage in the kidney as a necessary factor in the hemorrhage.

CASE IV.—The second case, S. G., boy, seven years old, had a nystagmus since birth. Except for this and repeated attacks of tonsillitis, the child had been well, until May, 1916, when the mother noticed the urine was of a bright red color. The urine showed both macro- and microscopically large quantities of blood. Physical examination showed the nystagmus and extremely large tonsils, with crypts wide open, a few of which showed cheesy débris and pus. The liver and spleen were slightly enlarged, but not tender. No other abnormal physical findings. Blood, Wassermann negative. Because of my recent experience with the previous case I advised tonsillectomy, which was done. The urine cleared up promptly, general improvement in the health of the child was also noticed, and no recurrence of the bleeding occurred during the next year, when the patient and family moved West.

CASE V.—The third case, W. M., age twenty-two. I saw the patient on August 30, 1919. He had been passing what appeared to be pure blood in the urine for a number of months. Felt extremely weak, tired, unable to work for several weeks, because of general debility. He stated that four years ago he had been refused life insurance because of some abnormal finding in the urine. Physical examination revealed a thin, rather sick looking individual, with a lemon yellow color of the skin. General physical examination: pupils react to light and accommodation; tongue pale, not fissured, normal moisture present; teeth clean, no pyorrhea, gums normal; tonsils submerged, hard on palpation, the pharynx pale; lungs normal; heart outlines normal, slight systolic murmur at the apex, transmitted upward and to the left; pulse 78; abdomen normal; liver and spleen not palpable, no tenderness anywhere. Extremities normal, except for slight muscular weakness. No pain or tenderness over the sternum, ribs, or long bones. Reflexes normal. Blood count: red cells 2,500,000, whites 4,000; Hb. 70 per cent.; color index 1 plus; blood smear; anisocytosis, polychromasia. No nucleated reds. Platelets appeared about normal in the smear. Blood, Wassermann negative; blood culture negative. Report of the bladder and kidney examination by Dr. M. B. McGonigle: essential hematuria. Gastric analysis showed total acidity 40; free HCl 20; no blood. Superficially the condition resembled pernicious anemia, but the normal condition of mouth and tongue, the absence of achylia and bone tenderness, the presence of a normal number of blood platelets, and the absence of spinal cord changes rule out this diagnosis. The injection of 10 c.c. of normal horse serum for three successive days failed to check the hemorrhage. Tonsils were then removed by Dr. J. J. Lasalle.

It is of interest to note that the pus in the right tonsil was evidently under greatly increased tension, for when the snare was tightened on the pedicle of the tonsil the pressure resulted in pus being forced out with so great a pressure that it shot past the face of the operator for a distance of at least two feet. The visible blood in the urine did not clear up within two weeks, and the patient became discouraged and sought advice elsewhere, despite the fact that I had warned him that I did not expect results in less than one to two months, because of the long standing of this condition.

After seeing a number of physicians he was again given some normal horse serum about six weeks from the time that the tonsils had been removed. Shortly after this the blood disappeared from the urine and the horse serum was given credit for the cure. However, I think it is safe to say that the disappearance of the infection after tonsillectomy is really responsible for the cure. I had a letter from this patient recently telling me that he is feeling well and gaining in strength right along.

These three cases are perhaps rather unusual and severe, but surely we must have gradations between this type of case and those in which we find just a few blood cells in the centrifuged specimen. Chronic interstitial nephritis is in many cases admittedly due to infection and toxemia. How many of these cases showing abnormal urinary findings in the fourth decade of life later come to us with all of the findings of a chronic interstitial nephritis? Probably a large number.

The association between infection in the tonsil and thyroid gland enlargement, both toxic and non-toxic, is a disputed one. There is sufficient evidence, however, to show that this is not an unusual association. Every general practitioner must have seen cases of simple goiter that have decreased in size very decidedly after the removal of infected tonsils. (I do not refer to the endemic goiter, prevalent in certain regions.) These cases

are too common for any dispute to arise. As to exophthalmic goitre, many surgeons are seeking out all sources of infection and removing these when found, oftentimes before the operation on the thyroid gland is done. One suggestive case might be related.

CASE VI.—Saw M. P., September 27, 1916. Six years ago complained of some pain in the right side of the abdomen, accompanied by vomiting and tenderness. Some soreness persisted on and off in this region until her appendix was removed one year later. During this time and since she has been very nervous, feels very tired, complains of soreness all over the body, and shakes all over. Appetite is excellent—in fact, she eats ravenously. Bowels move rather freely. Previous history negative, except for childhood diseases and repeated attacks of tonsillitis. Menstruation excessive and painful. Examination: expression of the face slightly anxious. Throat injected, tonsils large, red, crypts contain some cheesy débris, teeth in good condition. Thyroid gland uniformly enlarged. Soft bruit can be heard over the gland. Lungs negative, heart slightly enlarged to the left, apex being 10½ cm. from the mid-sternum line, sharp and thumping, systolic murmur at apex, transmitted upward and to the left. Pulse 150. Face and fingers cyanotic. No jerks except the fine course tremor in the hands and fingers. Temperature 99.4°. The patient was put to bed until the pulse came down to 110. On November 16 the tonsils were removed by Dr. A. L. Steinfeld. Patient improved gradually, so that at the end of two months her pulse was never over 90; she felt well, gained in weight and she was able to go to work for the first time in six years, and has remained well up to this time.

This perhaps is an unusual case, and such a result is not to be expected in every case. Of course, objection might be made that in the absence of metabolism tests this case might have been one of neurocirculatory asthenia. That, of course, is possible. However, it does not detract from the significance of the result. It is interesting that in this same family there were two cases, one the patient's mother, and a nephew, a boy of eight, who had daily drenching sweats, which were very exhausting, and persisted for a period in each case of about six months, before consent to removal of tonsils was given. Both were relieved by tonsillectomy.

Patients showing cardiac symptoms such as myocardial weakness and angina are not infrequently seen. Sir James Mackenzie[4], under the heading of "Toxic Angina," says in part. " . . . The more I see of them the less inclined I am to refer attacks of pain in women to a serious condition of the heart. I have laid down for my own guidance that women who suffer from attacks of angina under fifty years of age with no demonstrable signs of gross disease of the heart, suffer not from primary heart trouble but from some condition which produces general exhaustion, and the heart pain is an expression of the heart exhaustion, and serves as an indication to search elsewhere for the cause of the trouble."

These pains, Sir James Mackenzie finds, occur particularly in women with a hypersensitive nervous system. I have seen within the past year a patient of forty-six who suffered intense angina and a sense of exhaustion, who had distinctly infected tonsils and other signs of tonsillar infection, which I shall mention later. This patient refused tonsillectomy and after seeking counsel elsewhere has had her life limited, for over six months, to practically sitting about the house, because she is caught up by pain on slight exertion. Yet she has absolutely no demonstrable signs of heart lesion nor aortitis.

I have now under treatment a woman of fifty-five, whom I saw two years ago following an attack of tonsillitis, with a myocardial weakness, associated with slight edema and shortness of breath. At the present time she is suffering from another mild myocardial weakness, following another attack of tonsillitis, associated with joint pains. She has been considerably improved by the use of autogenous vaccines. The culture taken from the crypts of the tonsil showed a pure streptococcus. I might cite a great many such cases for they are very common.

Angina pectoris occurring during the period of rest is always suggestive of a focus of infection, and here again the tonsil must be carefully investigated, along with other sources of focal infection.

R. H. Babcock[5] calls attention to the necessity of examining carefully in cases of angina pectoris or apparent myocardial disturbances for some focus of infection in the mouth, throat, or digestive tract, and particularly emphasizes the association between heart weakness and gall-bladder infection. However, as many cases of gall-bladder infection are due primarily to tonsillar infection, the tonsils become important in these cases also. I have on several occasions seen patients with symptoms of extreme exhaustion, so extreme that it was an effort to raise the hand or the arm, they just wanted to be left alone, a peculiar ashen gray color of the face was noted, the lips were slightly cyanosed; this extreme exhaustion would last anywhere from one to three weeks; a temperature up to 99.5° was noted at times. At the end of this period in two cases that I can recall distinctly there occurred a chill, accompanied by rise in temperature to 103° F., with pain, tenderness, and rigidity over the gall-bladder, and associated with this was some soreness of the throat and tenderness in the glands of the neck. As soon as this attack subsided the patients' exhaustion disappeared and they were able to get up and about (Autovaccine?). Rehfuss[6] says of these gall-bladder cases: "These are the types associated with chronic appendical disease and they are the class in which gall-bladder infection occasionally is due to *primary focus of infection elsewhere* (italics mine.)"

It is possible that a large variety of skin conditions are due to foci of infection in various parts of the body. I have seen cases of psoriasis, infectious dermatitis, pompholyx, and other types of skin eruption clear up and remain so after the removal of badly infected tonsils. I do not mean to imply that all these conditions are invariably due to these infections, but that infection plays a part, I am convinced.

In determining whether tonsils are infected or not, certain things must be borne in mind. It is not sufficient to look in the throat to see if the tonsils are very large and inflamed in appearance. It is necessary either to hook the tonsil out of its fossa, or by retracting the anterior pillar to bring the tonsil into view. Then, by pressure, pus may

be expressed from the tonsil. The presence of a red, inflamed, or purplish looking anterior pillar nearly always indicates infected tonsils. Tonsils that have been subject to one or more attacks of peritonsillar abscess are usually infected. Small or submerged tonsils that show no visible crypts from which pus can be expressed are best examined with the finger. Palpation will show hard, shotty, and nobby masses within the substance of the tonsil. Perhaps this method of palpation is, all things considered, the best method for determining the presence of infection within the tonsil. For this method of palpating the tonsils I am indebted to Dr. Frank Smithies of Chicago.

These patients very frequently show, in addition to the other symptoms considered in this paper, occasional painful nodules in various parts of the body, especially over the external occipital protuberance, the breasts, and along the spine. I have seen these on a number of occasions over the sacroiliac region, and producing painful attacks which were attributed to sacroiliac disease. These nodules may show ecchymosis at some time during their presence. In size they vary from that of a pinhead to that of a pea. Their duration is from two weeks to several months. A history of having had these nodules can be elicited in a large number of these cases, and I consider this an important symptom. Another important symptom should be inquired about: nearly always, if asked, the patient will admit frequent stiffness and soreness of neck muscles (sternocleidomastoid) even if the throat does not get sore.

At the present time we are seeing an unusually large number of tonsillar infections, probably as a result of the activation of latent infections by the influenza epidemics which we have had in the past two years. Because of the emphasis recently placed upon teeth as a source of infection, it is not uncommon to see patients who have had their teeth rayed and suspicious teeth extracted, and other visible foci of infection examined without relief, show typically infected tonsils to which no attention has been paid. It is my impression, though of this I am not yet absolutely certain, as it is only recently I have given the matter any thought, that there is some difference in the manifestations of infection due to dental abscesses and those due to tonsillar infection. In a general way I would say that apical abscess is apt to produce trouble in one or two definite places in the body, such as a joint infection, iritis, etc., without making the patient feel bad as a whole. In cases suffering from tonsillar infections we nearly always find that they do not feel well besides suffering from joint pains, headaches, etc. They feel bad, are tired constantly, irritable, and have a number of minor complaints which are very suggestive. This differentiation deserves further study.

The frequency with which tonsils are now being removed in children will bear fruit in the coming generation. At the present time I think a more intensive study of the relationship of tonsillar infection to our overyday practice will result in considerable advance in our knowledge of the cause of a large number of conditions commonly seen in everyday practice.

Note.—Since going to press an article has appeared by L. A. Turley in the first number of the *Annals of Medicine*, showing that the tonsils removed at operation contain more bacteria per c.c. than are found in ordinary sewage. Where else in the body would this state of affairs be tolerated?

OBESITY.

BY HERBERT C. CLAPP, M.D.,
BOSTON, MASS.

EVERYBODY knows what obesity is, but very few can give an exact and satisfactory definition of it. A scientific man perhaps considers the collection of fat pathological when it interferes in any manner with the bodily activities of the individual, such as impairing locomotion, causing shortness of breath, palpitation, and disinclination to physical and mental exertion. We must admit that these are common effects, but all fat people do not necessarily show them. Those of us who have seen "Fatty Arbuckle" at the movies (and whó has not?) will give him credit for remarkable nimbleness of body and mind, and he acts as if he enjoyed it. It is hard to find a universally applicable standard of the proper relationship between normal height and weight, although elaborate tables can be found scattered through the books, and life insurance companies allow a variation of about twenty per cent. from these within the limits of health. Several short-cut rules are given for those who have no tables. Brinton thinks that a healthy adult male, 66 inches tall, ought to weigh a little over 140 pounds, and for every inch above and below this height we may respectively add and subtract about five pounds, also adding a little for advancing years. Moritz subtracts 100 from the height expressed in centimeters and takes the balance as a measure of the weight in kilograms. A woman's normal weight is supposed to be a few pounds less.

If any one desires to study the subject of Obesity historically, he can find an immense amount of material awaiting him in the larger libraries. The different degrees of it have been labeled as the *enviable*, the *comical*, and the *pitiable* stages; the first presenting itself as a pleasing rotundity, the second as a jovial embonpoint of the Falstaff type, and the third as a sad, unwieldy, and even disgusting deformity. We must not expect an agreement of opinion on the exact dividing lines. Many of the Hottentot women, for instance, have an immense accumulation of fat in the gluteal region, which is by their friends considered as a mark of great beauty; whereas some of our women with a small fraction of the enlargement make frantic efforts at hip reduction. It is entirely the point of view.

A short time ago the New York comic weekly *Life* had a very funny picture (it does occasionally) of a rotund and pretty young woman in a bathing suit at the beach, looking up and calling out to her husband who was just emerging from the bath-house in a very abbreviated suit, and who was so painfully thin as to be almost a skeleton: "That reminds me, Frank, did you think to buy those curtain poles?" This was apparently to call attention by contrast to her own plump and pleasing personality.

One of Dickens' most striking characters (or at any rate it so seemed to us in the days of our childhood) was his Fat Boy "Joe" in Pickwick, who spent his time in alternate eating and sleeping. He was once known (Dickens tells us) to defer eating to say to Mary, "How nice you do look!" "This was said (the author continues) in an admiring manner and was so far gratifying; but still there was enough of the cannibal in the young gentleman's eyes to render the compliment doubtful."

A well known critic says that Falstaff was the greatest comic character in dramatic writing.

The celebrated Sydney Smith, who was no light weight, said at one time in his memoirs: "The heat was so dreadful here that I found there was nothing left for it but to take off my flesh and sit in my bones."

In the Boston Medical Library is a curious English book about 100 years old, written by Dr. William Wadd, Surgeon Extraordinary to the King, who was himself an enormous man, and who collected a number of cases of corpulency with some pictures. His story of one is interesting. "On returning home after some years' absence I passed a man in the street without knowing him, although I had previously been well acquainted with him. He had from being as corpulent a person as I ever saw become altogether as thin. Upon inquiring what disease had wrought this effect on him, I found he had been in perfect health and continued so; but sheer poverty had laid its hand upon him and by depriving him of his usual good cheer produced the change."

We are thus forcibly reminded of numerous statements made by visitors to Germany during and after the late World War, all agreeing that a great many of the fat, greasy, beer-guzzling Germans formerly seen in the streets had been replaced by men worn thin by short rations.

In Gould and Pyle's "Anomalies and Curiosities of Medicine" (Phila., 1897) are gathered together many cases of extreme corpulency at all ages, showing clearly that "some men are born great, some achieve greatness, and some have greatness thrust upon them." Figure 168 represents Baby Chambers, a girl of 4 years, weight 256 lbs. A girl 5½ years weighed 250 lbs. Susanna Tripp at six weighed 203 lbs., was 3 feet 6 inches tall and 4 feet 2 inches around the waist. Another girl of 9 years weighed 201 lbs. Another girl of 11 years 200 lbs.

The most famous, apparently, of all fat men, was Daniel Lambert, who was born in Leicester, March 13, 1770. He was like other boys till he was 14 years old. I met him so often in all the encyclopedias and treatises I consulted, that finally I felt almost on terms of intimate acquaintance with him. At 39 years he weighed 739 lbs. and measured 9 feet around the body and 3 feet around the leg. Edward Bright, fat man of Essex, weighed 616 lbs.

On the tombstone of James Parsons, fat man of Teddington, who died March 7, 1743, it was written that he had often eaten at a meal a whole shoulder of mutton and a peck of hasty pudding. Another Englishman in Lincoln used to eat 18 lbs. of meat in a day and died at 28, weight 530 lbs. William Campbell, the landlord of the Duke of Wellington in Newcastle on Tyne, was 6 feet 4 inches tall, weighed 728 lbs., was 85 inches around the waist and 35 inches around the calf.

But why continue this list? It is like piling up Ossa on Pelion. It would be more interesting, if less profitable, to leave the realms of fact and soar to the altitudes of the imaginative giants of Greek antiquity or those of Gulliver's travels. But we now must content ourselves with stern realities.

Although obesity may occur at any age, it is oftenest found in the male sex between 40 and 50 years of age, and in the female between 30 and 50, at the time of life when everybody ought to eat less than formerly. It is rather more common in the female than in the male, perhaps on account of her generally quieter and more inactive life. It sometimes appears with the forced rest after a long illness like typhoid fever or pneumonia.

Anders recognized the influence of heredity in 60 per cent. of his 543 cases. Naturally habitual overeating is the big cause of obesity. This might seem to be an utterly unnecessary statement, were it not for the fact that some thin people eat enormously and remain thin, and that some very fat people deny that they are big eaters, and claim on the contrary that they eat very litle, and perhaps they really think so. At this claim we feel like smiling, and we think of the cat with her mouth covered with yellow feathers, while she says, "I have not seen the Canary bird all day." Although it is certainly incontrovertible that the great majority of cases of obesity *are* caused by a too great consumption of fat-forming foods, especially if accompanied by too little exercise, or in other words, that the energy taken in the food has exceeded the energy expended in the form of work, heat, etc., yet we have to admit that sometimes fat people *are* really very small eaters, although it is decidedly exceptional. In such cases we have learned to attribute the anomaly to the influence of the thyroid and perhaps some other glands of internal secretion. Surely thyroid hyperfunction causes loss of weight, while thyroid hypofunction tends to increase weight, as seen in myxedema and cretinism, on which account the dried thyroid is used largely as a medicine for reduction. The desirability of its use will be discussed later.

Now why should we try to remove the excessive flesh from fat folks? The principal argument which appeals to them is an esthetic one. It will improve their looks, and even if we do not like to pose as beauty doctors, it will appeal more or less to us also. Comfort is another desideratum, and the tendency to the development or aggravation of certain symptoms of disease appeals to us. Shortness of breath and palpitation are two of the most trying symptoms, and certain organic and functional diseases of the heart are apt to be produced or in-

tensified. Renal degeneration, arteriosclerosis, apoplexy, gout, rheumatism, gallstones, diabetes, and other troubles are clearly associated. If a patient has bronchitis, asthma, or pneumonia, their course is often affected for the worse. Obesity directly or indirectly shortens life. Fat people often have a great disinclination to mental or physical exertion, probably because a certain form of blood-poisoning results from the efforts of the organism to eliminate some of the extra and unnecessary food. A spontaneous cure is not very likely. The fatter one is, the less he wants to exercise, and the less he can exercise the fatter he gets. It is a vicious circle. When one has organic heart disease, obesity is a very trying and even dangerous complication, and judicious efforts should, if possible, be made for its relief, although it is a much more difficult problem than in uncomplicated obesity; and here prevention is far better than cure; and if the disease is far advanced, or the patient is well along in years, it is best to let his fat alone.

A diabetic should never be reduced in flesh, nor a sufferer from anemic obesity. In any case do not allow a patient to get weak during reduction. If he does, go more slowly or stop altogether. He ought to feel better instead of worse. Do not use a very rigid régime with the very young, and especially do not restrict protein, as this may interfere with proper tissue development of the growing child. Better treat the child before he has got very fat; and with the help of records of food kept by his mother, cut out some of the large amounts of sugars and starches that he undoubtedly gets. In the aged it is generally unwise to impose severe restrictions of diet. The most favorable cases to reduce are people of or under middle life and of good general health, who have not been fleshy very long.

In most cases it is wiser not to lose flesh too rapidly. One or two pounds a week will generally do very well, and even this should be kept up for not more than two or three months at a time, when a period of stationary weight should be allowed before reducing again. Very dangerous symptoms and even death have sometimes followed too violent efforts to lose large amounts of flesh in too short a time. Of course this statement does not apply to such cases as we occasionally read about, where a man said that in one day he had lost 130 pounds—when his wife eloped.

Treatment by Exercise.—Exercise is the most important factor in the treatment of Obesity, next to the regulation of the diet, but it must not be carelessly prescribed offhand in any case without a thorough examination of the heart, kidneys, etc., as dangerous and even fatal results may follow. Most of the causes of death in obesity are due either directly or indirectly to diseases of the heart and arteries, and their condition must be to a great extent our guide in the use of such a powerful agent as exercise. If they are sound, it can be employed freely. If not, the greatest caution is necessary, or it must not be used at all. Naturally young adults bear it better than the old, and they who resume it after a short intermission better than those who have taken no exercise for many years. Many fleshy professional and mercantile people are sedentary, while a street laborer is seldom fat. So the patient's previous habits should be considered as well as the state of his internal organs; and if he has been indolent for years, he should take up physical exercises very gradually and under careful supervision. He can often find competent teachers in a good gymnasium who will help him reduce. Where the abdomen is especially protuberant, many people have reduced it by the well known exercise of lying on the back and slowly rising to the sitting position, or lying on the back and raising the legs. All exercise should be progressive, regular, and adapted to the individual needs of the patient. Walking is one of the best, the distance to be gradually increased.

In spite of the fact that many fat people die from overexertion on account of heart disease, nevertheless exercise has long been used as a *remedial* measure in diseases of the heart. In advanced disease the famous resistance exercises of the Schott Brothers at Bad Nauheim and of other physicians, coupled with the carbonated brine baths, have often been helpful. Before this, in earlier cases, but after the stage of dyspnea had been reached, back in 1854, the big Stokes wrote advising a system of graduated muscular exercise for debility of the heart, which is often "removable by a regular course of gymnastics or by pedestrian exercises, even in mountainous countries, as Switzerland or the Highlands of Scotland."

But the great champion of exercise as a heart-cure was the German Oertel, who first cured himself and then others, as a result of his own experiences, as told by Tait McKenzie in his book on "Exercise" (1915). His motto was "Function makes Structure." His system combined walking and hill climbing with restriction of fluids, the hills being of different degrees of steepness; and he gradually increased the length of time spent and the steepness of the slope, always carefully watching the patient.

At thirty years of age he himself was fat, with dyspnea, cyanosis, edema of the legs, and diminished urine, which obliged him to give up practice. In 1875 he went to the mountains and experimented on himself throughout August. On the first and second days he took short excursions in the morning and afternoon on level ground, and climbed a hill 100 meters high. Breathlessness and palpitation made him stop after twenty steps on a level and ten steps up hill, and he perspired. On the third day he climbed a hill 157 meters high and almost suffocated. His exercise lasted six hours and he lost much weight from perspiration; but that night he had neither irregularity nor palpitation. In the second week he climbed a hill 527 meters high in four hours and stopped and rested about 150 times. No evil effects followed. He thirsted, but he only gargled. After four weeks his exercises were longer but easier. In six weeks he returned to Munich and resumed practice, after losing eight kilograms. His pulse was normal and he could climb two flights of stairs. For eighteen years thereafter he alternated training and rest and got along pretty well. He established a cure at Reichenhall for the treatment of these diseases. He published a map of his grounds, which were extensive and very hilly, with walks painted some red, some purple, some green, and some yellow, to

indicate different degrees of steepness. He had also proper stations, rest benches, and trees painted in colors. In this country a well known sanatorium is said to have established similar walks.

Here again, if we could only see it in time, prevention is better than cure.

Dietetic Treatment.—Since we all agree that obesity is caused in the majority of cases by overeating, it naturally follows that to remedy this condition we must restrict the diet, or in other words, we must prescribe partial starvation for a time.

The fat in our tissues is formed mostly from the carbohydrates (sugars and starches) which we eat, largely from the fats, animal and vegetable, in our food, and to a slight extent, under certain conditions, from the protein; while our muscular tissue is derived only from the protein. Therefore it is obvious that in restricting the diet we must cut out particularly the sugars, starches, and fats. Still, we must not allow this fact to make so much impression on us as to forget that the *quantity* of the food eaten is even more important than its *quality.* A fat person often argues that the amount of the food he eats is really very small. Nevertheless, if he is gaining in weight, he must be consuming too much, and it must be cut down. The most important thing is to reduce the total number of calories, regardless of what class of foods they come from. This is proved by the occasional success of each one of several reduction methods containing different proportions of these classes. Individuals differ likewise.

At the beginning of treatment the patient naturally misses his usual food and acutely feels the hunger which is less obvious later. He can to some extent be consoled by eating largely of such foods as contain little carbohydrate but plenty of cellulose, and are likewise *bulky;* such as fruits, green vegetables, sauerkraut, etc. In this way he lives partly on foods which produce little fat, and yet he has plenty in his stomach to allay the pangs of hunger. If he is faint between meals, he can have a little thin soup, buttermilk, tea, skimmed milk, or fruit. While he is reducing, the patient lives on his own fat, as the saying is, which supplies some of his energy and heat. He would do well to continue under the observation of his physician, instead of trying to run his own case. He should weigh himself once a week, and sometimes every day, at the same hour, if possible, and with bladder and bowels empty. He should, at the beginning of his treatment, at least, keep a careful record of all the food and drink he takes, for the inspection of the doctor.

Many physicians require their patients to weigh accurately each article of food at the table, and make a record of it; but this is very burdensome, and it generally answers all practical purposes for the patient, after a short course in weighing food (in order to accustom his eyes to size and weight), to adopt a frequently-used phraseology, such as, for instance, three tablespoonfuls, two teaspoonfuls, one egg, one roll, one slice of bread, half a grape-fruit, etc., from which can be approximately figured their weight and also their calories, by means of E. A. Locke's very ingenious and praiseworthy "Tables of Food Values" (D. Appleton & Co., N. Y., 1911).

In beginning a reduction it is often pleasing to the patient and therefore good policy to do so *gradually,* in order not to give him too much of a jog all at once. It takes a good deal of courage and perseverance to reduce anyhow.

As far as possible, the normal amount of protein should remain in the diet, or should sometimes be decidedly increased; because it produces so little fat and is protective to the vital tissues, and makes the nccessary restriction of other foodstuffs more endurable. But when the kidneys are not functioning perfectly, it is not wise to strain them by too large a proportion of protein. Also too much of this may cause indigestion and gout in some cases.

Reduction Methods.—Although the subject is a very old one, yet its present study very seldom goes back farther than to 1863, when the since world-renowned Banting first introduced himself to the admiring gaze of that portion of the population which finds itself too amply upholstered. Any article on Obesity which omits mention of Banting is like the play of Hamlet with Hamlet left out. He was 66 years old, 5 feet 5 inches tall, and weighed 202 pounds instead of his proper 142. He was always puffing and blowing and was obliged to go down stairs slowly and backward. He wrote a little book on Corpulence, and explained that his physician, Dr. Wm. Harvey, had cured him by a diet as pleasant as it was effectual, although many fail to find much pleasure in it. He had previously tried in vain violent exercises and Turkish baths. In 38 weeks he lost 37 pounds, and in nine months all his unpleasant symptoms had disappeared under the following diet:

Breakfast: 4 oz. of meat (not pork) or fish, 1 cup of tea without milk or sugar, 1 oz. of dry toast. *Dinner:* 5 oz. of any meat except pork, or any fish except salmon, any vegetable except potato, fruit, 2 or 3 glasses of claret or sherry. *Tea*: 2 oz. of fruit, one rusk, 1 cup of tea. *Supper*: 4 oz. meat or fish, 1 glass of claret. This diet has been criticised as being too nitrogenous. It contains about 172 grams of protein, 250 grams fruit and vegetables, 90 grams of bread, and 1020 c.c. fluids; or about 1200 calories.

Other apostles of dieting followed, among whom one of the most prominent was Ebstein, who differed by allowing an abundance of fat, arguing that it diminished the craving for food and drink, and that therefore the total intake of food was less. The objection to Ebstein's method is that the extra fat may have accomplished its object by more or less upsetting digestion, which is not desirable.

Dancel and others diminished the amount of *fluid,* allowing not more than 6 to 12 ounces at a meal, making it a relatively dry diet, and not much between meals. The sensible view is that only a small amount of fluid should be taken *with* meals, as more at that time increases the desire for food; but that plenty should be taken 2 hours or more after a meal, and up to half an hour before a meal; a good amount being necessary to flush out the kidneys, especially with a relatively increased nitrogenous diet.

Weir Mitchell prescribed *skimmed milk,* at first with other food and then after a week without it. When we find how much skimmed milk will sustain the weight, we diminish the amount by degrees until the patient is losing half a pound a day. Rest and massage are also employed.

Reduction of Calories.—I think that the most widely prevalent feeling today is in favor of a modification of the methods of Von Noorden, who advises that since by general consent an average man needs about 3,000 calories of energy a day for heat and work, we can put our case for reduction into any one of the three following groups, according to what we want to do and how rapidly we want to do it.

First, we can reduce the calories by 1-5, making 2,400. Cut down sugar, fats, and cereals. If exercise is combined, this plan will succeed, but only slowly. *Second,* reduce by 2-5, making 1,800 calories. Cut out more fat and reduce bread. This plan also needs the help of exercise. It is also somewhat slow, but Von Noorden prefers it to the next, because there are no disagreeable consequences and it is safer. *Third,* reduce by 3-5, making about 1,200 calories. This group includes all the classical systems of diet:

	Protein Grams.	Carbohydrates Grams.	Fat Grams.	Calories.
Banting	172	81	8	1,100
Ebstein	102	47	85	1,300
Oertel	170	120	45	1,600
Von Noorden	155	112	28	1,366

Von Noorden gives 8 small meals a day and restricts the fats more than the carbohydrates, but some of the meals are hardly worthy of the name, for one is one egg, one a cup of soup, one a cup of coffee, and one a glass of skimmed milk.

As these are all starvation methods, it is never safe to continue them more than a few weeks at a time, and the patient's heart and kidneys should be carefully watched. Avoid too great a variety of food, as it tempts the appetite.

After the active treatment, the patient should try to eat only enough to hold the weight stationary for a while. If he gains in spite of this, he might have a "fast" day once a week in which he takes only a quart of milk.

If the fat person has also gout, the protein should be reduced and foods rich in purin should be avoided. In edema, fluids and salt should be restricted.

When one studies the composition of foods and calories, the menus can be made up from the tables in different ways and changed more or less from day to day, to secure a little variety.

A man or a woman needs to be a hero to stick to it right along without complaint, and no wonder that many fall by the wayside in discomfiture through lack of courage and persistence, and in disgust give up trying to be thin.

I copy three menus from Da Costa's "Handbook of Treatment," which are said to give daily calorie values of 1,000, 1,500 and 2,000, but which I think come nearer to 1,100, 1,400 and 1,900.

I. (1,100 calories). *Breakfast:* ½ orange, 1 egg, butter 1 ball, 1 roll, ½ cup coffee with ¼ grain saccharin, if wanted, but no milk or cream, ½ glass hot milk.

Lunch or *Supper*: 1 cup tea and lemon (saccharin), 1 slice cold veal, salad made of lettuce, ½ apple, 3 almonds and French dressing, 1 tablespoon of calf's foot jelly.

Dinner: Bouillon 4 oz., celery 3 sticks, lean roast beef 1 slice, 1 onion, spinach 2 tablespoons, ½ egg, cottage cheese; stewed strawberries 1 tablespoonful.

II. (1,400 calories). *Breakfast:* 1 apple, 2 eggs, 1 ball of butter, 1 roll, ½ cup coffee, ½ glass of milk, sugar 1 cube.

Lunch or *Supper*: 1 cup tea and lemon, sugar 1 cube, cold chicken 1 slice, asparagus, French dressing.

Dinner: 6 oysters, 3 sticks celery, mutton chop, squash 2 tablespoonfuls, ½ egg, Swiss cheese 1 slice, ¼ cantaloupe.

III. (1,900 calories). The same as II. with the addition of one roll and butter, 1 potato, and soft custard to the dinner.

From the same source comes a tabulation of the following articles of food, each article being followed by 2 figures, the first representing the weight in grams and the second the calories.

Fruits, raw and stewed without sugar: Apple 150-72. Blackberries 100-59. ¼ cantaloupe, 230-45. Cherries 100-76. Currants 100-59. ¼ Grapefruit 150-69. Grapes 75-56. Huckleberries 100-76. ½ orange 125-48, Peach 125-42. ½ Pear 75-42. Pineapple 2 slices 100-44. Plums 35-29. Raspberries 50-28. Strawberries 100-40. Watermelon 300-39.

Fruits to be avoided by fat people: Bananas, dried fruits, preserves, jams, jellies, marmalade.

Meats (fowl and fish): Lean roast beef 100-111. Beef round (no fat) 100-185. Sweetbread 80-135. Roast chicken 100-180. Lean boiled mutton 75-126. Lean mutton chop 100-135. Lean ham 33-93. Boiled cod 100-98. Boiled haddock 100-108. Boiled halibut 100-121. Eggs 50-80, except scrambled, fried, and omelettes.

Meats to be avoided by fat people: Beef tenderloin, tongue, capon, bacon and pork, turkey, goose, duck, bluefish, mackerel, salmon, eels, sardines, fat meats in general, hashes, sausages, fried meats.

Vegetables: String beans 60-13. Beets 70-29. Beet greens 100-54. Cabbage 100-5. Carrots 100-18. Cauliflower 100-7. Celery raw 50-9. Canned corn 100-101. Green corn 100-100. Cucumbers 50-9. Dandelion greens 100-63. Raw mushrooms 50-23. Onions 100-42. Parsnips 100-10. Baked potato special 100-114. Squash 100-69. Spinach 100-57. Canned tomatoes 70-16. Raw tomatoes 70-16. Radishes 100-23. Turnips 100-4.

Vegetables to be avoided by fat people: Beans, corn, peas, potato, hominy, rice, maccaroni.

Soups and shell fish: Beef soup 120-32. Bouillon 120-13. Consommé 120-16. Canned vegetable soup 120-17. 6 raw clams 100-47. 6 raw oysters 85-44.

Soups to be avoided: Bean, oxtail, green and mock-turtle, pea, tomato; also cream soups, stews, and chowder.

Also prohibited or restricted: all fatty foods, butter, cream, olive oil, pastry, fried food, rich sauces, puddings; sugar and all sweets, candies, cake, starchy foods, thickened sauces and gravies. Desserts, ice cream, alcohol.

Saccharin as a substitute for sugar is now considered by the best authorities to be perfectly harmless, in spite of the theoretical opposition to it.

Medicine.—With the exception of thyroid extract, there is no medicine to be counted on to reduce flesh, in spite of all the specious advertisements in the newspapers. Patients should of course be prescribed for symptomatically for indigestion, headache, pain, or whatever else ails them, but not for the distinct purpose of taking off the flesh.

Thyroid extract certainly will do this in many cases, but in the opinion of some of the best authorities the game is hardly worth the candle, on account of the associated dangers. If it is employed at all, its use should be confined to those cases of obesity which seem to be the direct result of thyroid deficiency, rather than to the general run.

A BACTERIOLOGICAL STUDY OF RESPIRATORY INFECTIONS AND RESPIRATORY CONTACTS AS ENCOUNTERED IN THE AMERICAN EXPEDITIONARY FORCES, FRANCE.*

By HUGH R. SPENCER, M.D.,

BALTIMORE, MD.

PROFESSOR OF PATHOLOGY, UNIVERSITY OF MARYLAND SCHOOL OF MEDICINE AND COLLEGE OF PHYSICIANS AND SURGEONS.

THE work upon which this paper is based was carried out during the months of September, October, November, and December, 1918, while the author was attached as pathologist to U. S. Army Laboratory No. 1, A. E. F., France. The material for study was obtained from the cases coming to autopsy at the neighboring Base and Camp hospitals and from the medical officers, nurses, and attendants in the same hospitals. The series of studies from autopsies embraces seventy-five cases, all of which showed an infection of the respiratory tract in the form of a pneumonia. The autopsies were in all instances performed within a few hours after death, and smears and cultures were made at the time of autopsy.

In this series a special study was made as to the cause of admission to the hospital, the part or parts of the lungs involved, the incidence of complications and the types of microorganisms associated with the lesions.

In table I the seventy-five cases studied at autopsy are tabulated as to the cause of admission to the hospital, the diagnostic terms were taken from the cards that accompanied the body to the morgue.

TABLE I.

	Per Cent
Influenza	40.3
Pneumonia	33.3
Gunshot wounds of extremity	6.6
Acute bronchitis	4.0
Gassed	2.6
Acute tonsillitis	1.3
Diphtheria	1.3
Tuberculosis, pulmonary	1.3

A consideration of the data in table I shows that but 33.3 per cent. of the cases entered the hospital with recognized signs of pneumonia and that 66.6 per cent. of the cases developed recognizable signs of pneumonia while in the hospital. Since these infections occurred at a time when the so called epidemic influenza was prevalent, a rather careful study was made of the available histories, and it was found that 87.9 per cent. of the cases, i.e., those with a diagnosis of influenza, pneumonia, acute bronchitis and acute tonsillitis, showed a symptomatology more or less characteristic of the so called epidemic influenza.

In three of the cases of gun shot wounds of the extremity, a blood culture taken before death showed the presence of microorganisms in the blood stream and subsequent autopsy disclosed an osteomyelitis as the probable point of entrance of the microorganisms. In the other two cases of gun shot wound of the extremity, the pneumonia developed after a rather prolonged stay in the hospital, microorganisms were not found in the blood stream nor was there evidence of an osteomyelitis. These cases were probably terminal pneumonias.

In the two instances where the patient entered the hospital after having been exposed to the fumes of "mustard" gas, there was a severe fibrinopurulent inflammation of the entire upper respiratory tract, a purulent bronchiolitis and a purulent bronchopneumonia.

Table II is taken from the anatomical diagnosis at autopsy, and in it is tabulated the incidence of occurrence of lobar and bronchopneumonia. Only those cases which showed a consolidation of a definite lobar type were put down as lobar pneumonias, the term bronchopneumonia is used to cover those cases where the areas of consolidation were patchy and also those cases where there was an extensive exudation of fluid into the lungs where the areas of consolidation were indefinite or difficult to outline.

TABLE II.

	Per Cent
Lobar pneumonia	8.0
Bronchopneumonia	91.9

The following tables indicate the incidence of involvement of the right lung, the left lung, of both lungs and of the individual lobes of the lungs. Table III shows the incidence of involvement of the right lung, the left lung and the combination of both lungs.

TABLE III.

	Per Cent
Right lung alone involved	14.6
Left lung alone involved	8.0
Both lungs involved	77.3

These figures indicate that in this series of cases, in the majority of instances the lesions were found to involve both lungs and that of the two lungs the right lung was more frequently affected.

Table IV is composed of cases where the right lung was alone involved and shows the incidence of involvement of the various lobes and combinations of the various lobes.

TABLE IV.

	Per Cent
Right lung alone involved:	
Upper lobe alone involved	9.0
Middle lobe alone involved	0.0
Lower lobe alone involved	0.0
Upper and middle lobes involved	18.1
Upper and lower lobes involved	36.3
Middle and lower lobes involved	9.0
Entire lung involved	27.2

Table V gives the incidence of involvement of the lobes of the left lung, where the left lung was alone affected.

TABLE V.

	Per Cent
Left lung alone involved:	
Upper lobe alone involved	0.0
Lower lobe alone involved	66.6
Both lobes involved	33.3

Table VI shows the incidence of involvement in instances where both lungs were affected, note is made of the various combinations and of the frequency with which each combination occurred.

*Published by permission of the Surgeon General, U.S.A., Washington, D. C.

TABLE VI.

	Per Cent
Upper and lower lobes—left lung; upper, middle and lower lobes—right lung	24.6
Lower lobe—left lung; middle and lower lobes—right lung	18.9
Lower lobe—left lung; upper, middle and lower lobes—right lung	13.7
Lower lobe—left lung; lower lobe—right lung	13.7
Upper and lower lobes—left lung; lower lobe—right lung	8.6
Lower lobe—left lung; upper and lower lobes—right lung	5.1
Upper and lower lobes—left lung; middle and lower lobes—right lung	5.1
Upper and lower lobes—left lung; upper lobe—right lung	3.4
Upper and lower lobes—left lung; upper and lower lobes—right lung	1.7
Upper lobe—left lung; upper and middle lobes—right lung	1.7
Upper lobe—left lung; upper lobe—right lung	1.7
Lower lobe—left lung; lower lobe—right lung	1.7

This table indicates the wide dissemination of the infection throughout both lungs and shows the tendency toward involvement of the lower lobes.

Table VII gives the incidence of occurrence of the following complications:

TABLE VII.

	Per Cent
Pleurisy	72.0
Fibrinous pleurisy	56.6
Serofibrinous pleurisy	33.9
Fibrinopurulent pleurisy	9.4
Empyema of middle ears and sinuses	6.6
Pericarditis, acute	5.3
Peritonitis, acute	5.3
Endocarditis, acute	4.0
Meningitis, acute	4.0

The results of the bacteriological examination of the lesions of the lungs at autopsy are recorded in the following tables. Table VIII shows the frequency with which the various micro organisms alone or in combination were encountered.

TABLE VIII.

	Per Cent
Pneumococcus	84.0
Staphylococcus aureus	57.4
Streptococcus hemolyticus	28.0
Pfeiffer's bacillus	26.6
Staphylococcus albus	9.3
Diphtheria bacillus	6.6
Meningococcus	4.0
Tubercle bacillus	2.6

Table IX indicates the various combinations of micro organisms encountered and the frequency with which these combinations were noted.

TABLE IX.

	Per Cent
Pneumococcus + *Staphylococcus aureus*	25.3
Pneumococcus + Pfeiffer's bacillus + *Staphylococcus aureus*	14.6
Pneumococcus + *Streptococcus hemolyticus* + *Staphylococcus aureus*	10.6
Pneumococcus + *Streptococcus hemolyticus*	9.3
Pfeiffer's bacillus + Pneumococcus	5.3
Pneumococcus + Pfeiffer's bacillus + *Stapyhlococcus albus*	5.3
Pneumococcus alone	5.3
Pneumococcus + Diphtheria bacillus	2.6
Staphylococcus aureus + Diphtheria bacillus	2.6
Pneumococcus + *Staphylococcus albus*	2.6
Streptococcus hemolyticus + *Staphylococcus aureus*	2.6
Tubercle bacillus alone	2.6
Streptococcus hemolyticus alone	2.6
Diphtheria bacillus	1.3
Pfeiffer's bacillus	1.3
Pneumococcus + *Streptococcus hemolyticus* + *Staphylococcus aureus* + Meningococcus	1.3
Pneumococcus + *Streptococcus hemolyticus* + Peiffer's bacillus + *Staphylococcus aureus*	1.3
Pneumococcus + Meningococcus	1.3
Pneumococcus + *Staphylococcus aureus* + Meningococcus	1.3
Pneumococcus + *Streptococcus hemolyticus* + *Staphylococcus albus*	1.3

From a consideration of tables VIII and IX it will be noted that the pneumococcus was the organism most frequently encountered. It is unfortunate that in a number of the cases the type of the pneumococcus was not determined. In twenty of the cases where the organism was typed it was found that type I occurred four times or 19.04 per cent.; type II occurred four times, or 19.04 per cent.; type III occurred once or 4.71 per cent.; type IV occurred twelve times, or 57.14 per cent.

These figures would tend to indicate that in this series of fatal pneumonias, type IV pneumococcus was encountered more frequently than the virulent type I, II and III. The staphylococcus aureus was also frequently encountered, as indicated in the above tables.

The streptococcus hemolyticus and Pfeiffer's bacillus were found in 28.0 per cent. and 26.6 per cent. of the cases, respectively. The streptococcus hemolyticus occurred alone in 2.6 per cent. of the cases, and Pfeiffers' bacillus occurred alone in 1.3 per cent. of the cases.

Bearing in mind the incidence of occurrence of the various microorganisms as noted in the bacteriological examination of the lungs in the fatal cases of pneumonia as recorded in the previous tables, it seemed at least worth while to study the incidence of carriers of the pneumococcus, streptococcus hemolyticus and Pfeiffer's bacillus among the personnel at the various hospitals in which the fatal cases tabulated above were studied. To that end cultures were made from the tonsils and nasopharynx of the medical officers, nurses and attendants in both the medical and surgical wards of these hospitals. Sixty-one cultures were studied, of which twenty-five were from the medical wards and thirty-six were from the surgical wards.

Table X is taken from a study of the cultures obtained from the medical wards.

TABLE X.

		Per Cent
Number of cultures studied	25	
Cultures in which the pneumococcus was found, 19, or	76	
Types of pneumococci encountered:		
Type I	4 cases	21.0
Type II	1 case	5.2
Type III	0 case	0.0
Type IV	14 cases	73.6
Cultures in which the hemolytic streptococcus was found—5, or		20.0
Types of hemolytic streptococci:		
Streptococcus pyogenes	1 case	20.0
Streptococcus anginosus	2 cases	40.0
Streptococcus hemolyticus II	2 cases	40.0
Cultures in which Pfeiffer's bacillus was found, 7 or		28.0

Table XI is taken from a study of the cultures obtained from the surgical wards.

TABLE XI.

	Per Cent
Number of cultures studied	36
Cultures in which the pneumococcus was found, 22 cases, or	61.0

Types of pneumococci encountered:		
Type I.	1 case	4.5
Type II.	0 case	0.0
Type III.	0 case	0.0
Type IV.	21 cases	95.4
Cultures in which hemolytic streptococci were found, 4 cases, or		11.1
Types* of hemolytic streptococci:		
		Per Cent
Streptococcus pyogenes	3 cases	75.0
Streptococcus anginosus	1 case	25.0
Cultures in which Pfeiffer's bacillus were found, 9 cases, or		25.0

Table XII is taken from the combined study of cultures from the medical and surgical wards.

TABLE XII.

Number of cultures studied		61
		Per Cent
Cultures in which the pneumococcus was found, 41 cases, or		67.2
Types of pneumococci encountered:		
Type I.	5 cases	12.1
Type II.	1 case	2.4
Type III.	0 case	0.0
Type IV.	37 cases	85.3
Cultures in which hemolytic streptococci were found, 9 cases, or		14.7
Types* of hemolytic streptococci:		
		Per Cent
Streptococcus pyogenes	4 cases	44.4
Streptococcus anginosus	3 cases	33.3
Streptococcus hemolyticus II.	2 cases	22.2
Cultures in which Pfeiffer's bacillus was found, 16 cases, or		26.2

*Classification of streptococci based upon fermentative sugar reactions.

In a comparison of the results of the examination of cultures from the medical and surgical wards, it is interesting to note that the pneumococcus was encountered in 76 per cent. of the cases in the medical wards, as against 61.1 per cent. in the surgical wards, and that the more virulent types I and II were found more frequently in the medical wards.

Hemolytic streptococci were likewise found more frequently in the medical wards, an incidence of occurrence of 20 per cent. against 11.1 per cent. in the surgical wards. Distribution of Pfeiffer's bacillus seemed rather general, this organism being found in 28 per cent. of the cases in the medical wards and 25 per cent. of the cases in the surgical wards.

From a study of the above cultures, from individuals who were in the epidemic area and who were in more or less constant close contact with fatal cases of pneumonia, it will be noted that the pneumococcus was found in 67.2 per cent. of the cases examined, and that type I pneumococcus occurred in 12.1 per cent. of the cases, type II pneumococcus in 2.4 per cent. of the cases and that type IV pneumococcus occurred in 85.3 per cent. of the cases; in contrast it will be noted that the cultures from the lungs in the fatal cases of pneumonia, that the pneumococcus was encountered in 84 per cent. of the cases, and that of the cases typed, 19.4 per cent. were of type I, 19.4 per cent. were of type II, 4.71 per cent. were of type III, and 57.14 per cent. were of type IV.

It will also be noted that hemolytic streptococci were encountered in 14.7 per cent. of the cultures from contacts, as against 28 per cent. from the cultures in the fatal cases at autopsy.

Pfeiffer's bacillus was encountered in 26.2 per cent. of the contacts and in 26.6 per cent. of the cases of fatal pneumonia.

In conclusion it will be noted that:

1. Of the fatal cases of pneumonia studied in this series, 91.9 per cent. had bronchopneumonia.

2. Of these bronchopneumonias, the lesions were most frequently bilateral, and involvement was most often noted in all of the lobes of both lungs.

3. Of the lobes involved, the lesions were commonly found in the dependent portions.

4. Of the complications, pleurisy was the most common, being noted in 72 per cent. of the cases.

5. Of the organisms encountered, the pneumococcus, *Staphylococcus aureus*, *Streptococcus hemolyticus*, and Pfeiffer's bacillus were most frequently noted.

6. While in both the fatal cases of pneumonia and in the contacts, type IV pneumococcus predominated, the more virulent types I, II, III were noted more frequently in the pneumonia cases than in the contacts.

7. The number of carriers among the contacts was high, and, as might be expected, the incidence of carriers in the medical wards was greater than in the surgical ward.

8. Pfeiffer's bacillus was encountered as often among the carriers as in the fatal cases of pneumonia.

TREATMENT OF ACUTE POLYARTHRITIS.

METHODS OF PRACTICAL VALUE TO THE GENERAL PRACTITIONER AS DEVELOPED AT THE MONTEFIORE HOME AND HOSPITAL.*

By SAMUEL W. BOORSTEIN, M.D.,

NEW YORK.

INSTRUCTOR IN ORTHOPEDIC SURGERY, FORDHAM UNIVERSITY MEDICAL SCHOOL; ADJUNCT VISITING ORTHOPEDIC SURGEON, MONTEFIORE HOME AND HOSPITAL; CHIEF OF ORTHOPEDIC DEPARTMENT, FORDHAM HOSPITAL, O. P. D.; ADJUNCT ASSISTANT VISITING SURGEON, FORDHAM HOSPITAL.

WHENEVER some scientific work carried out at an institution, research laboratory, or hospital is presented before general practitioners, it is done with a different aim than if the same is presented at a meeting of research workers or specialists. To the general practitioner it must serve a double aim. It must review briefly the character of the work, the conclusions, and then dwell especially on how the physician can make use of this scientific advance in his own private practice. With these two phases in view, I will summarize the methods we have used at the Montefiore Home and Hospital on the service of Dr. George R. Elliott and show exactly how to apply these various methods with success in your own private practice.

So much has been written lately about polyarthritis, or what used to be called "arthritis deformans," dwelling on the focus of infection, that when the general practitioner strikes a chronic case or even an acute case, he is at a loss what to do and justly thinks: "What is the use? That cannot be carried out at home; the patient should be admitted at once to a special institution as the Montefiore." As the beds in such institutions are rather limited, he meanwhile feeds his patient on salicylates, till the sufferer, disgusted with the treatment, calls another physician, with the same result.

You are acquainted with the theories that the cause of polyarthritis is probably an infection and

*Read before the Eastern Medical Society, March 12, 1920.

that there is not any one focus which we can blame more than another. It is therefore your duty when you see the patient so early to look for the source or sources of infection and clear them up if you can. In the very acute cases, this can be done with more success than in the chronic cases that come before the specialists.

We may compare this disease with any other illness of serious or not serious nature. The physician is called in to attend a small child who has fever and is uncomfortable. He goes over carefully the heart, lungs, abdomen, looks into the throat, and peeps into the ear. Finally, he imagines he has found the culpable place, let us say the throat or abdomen. He gives to this the proper attention and the symptoms clear up. Sometimes, however, the symptoms remain stationary, or on the contrary, they have become aggravated. Then he knows that either the diagnosis was wrong or the medicine was not right and he corrects one or both. Sometimes he pays attention to all the tracts which might be responsible. He administers a purgative, attends to the kidneys, gives instruction as to the throat, nose, and ears, reduces the fever, and raises the resistance power. Only if all these fail does he call in a consultant or send the patient to a hospital.

Exactly the same should be done in these cases. Do not be satisfied with stopping at the bad condition of the patient's teeth. Examine the throat; infected tonsils even if not enlarged are more often the cause of infectious arthritis. The intestinal tract often harbors organisms and it is easy to guess whether there is constipation or stasis and guard against that. The genito-urinary tract can easily be examined in the routine. Every physician tests the condition of the patient's kidneys and genital organs, and he should simply go more into details in case of infectious arthritis. The heart and lungs are of course always examined by a good physician. Naturally when he finds indefinite signs in these foci, he may have to resort to a specialist later on, but at his first visit he can do that himself. Remove all sources of infection as soon as possible, even if you are not sure that they are the causes. Do not order your patient to have his teeth extracted but have him attended by his own dentist, and by all means avoid the common mistake that if all teeth are extracted he will be cured of his ailment.

General Treatment.—(*a*) Environment: As long as the patient is guarded against exposure to cold and moisture he may be kept in the city. There is no special advantage in seashore, water spas, or mountains.

(*b*) Combating the Infection: As in all infectious diseases, increase the elimination of all toxins by the natural channels, hence the intestinal tract should be cleansed. In the beginning, give a strong purgative, then laxatives should be given (mineral oil may be used freely). It is probably also advisable to give enemas or high colonic irrigations daily if the temperature is above normal. Diuretics should be given freely. Antipyretics should be avoided.

(*c*) Diet: There is no reason why any kind of meat should be withheld even during the acute stage. On the contrary, the patients need a full nutritious diet to combat the infection. Meats should be used freely. Our rule has been to give the patient any kind of meat, as much as he wants, prepared in whatever form he enjoys, provided it does not constipate him. Give him plenty of milk and fruit (cooked or raw), buttermilk two or three glasses a day (this prevents intestinal fermentation).

(*d*) Medication: All forms of salicylates, even aspirin, should be avoided. They upset the digestion and make the condition worse. Only those medicaments aimed to promote digestion, proper bowel activity, proper circulation, and proper character of the blood should be used. It is therefore advisable to give strychnine, arsenic, iron preparations, and phosphates. The laxative desired can be easily added to these. In chronic cases, cod liver oil can be added. During the acute or subacute stage, hypodermic injections of sodium cacodylate, given every four or five days in ¾ to 1¼ grain doses, have been found of great help in raising the resistance power. Tincture of gelsemium m. V. (0.3 c.c.) *t.i.d.* may be used to relieve temporary severe pain. It has been used freely in our cases with some benefit. If intestinal putrefaction is present, we used guaiacol carbonate, gr. v. (0.3 c.c.) *t.i.d.* None of the lithia or radium waters have been found of any value.

(*e*) Glandular extracts of almost all ductless glands of the body have been used by us with no appreciable benefit. We have abandoned them completely. Only occasionally in women we still use ovarian extract when the disease begins at the menopause, but we have very little faith in that.

(*f*) Vaccine Treatment: A great deal has been written on and many patients abused by vaccine treatment. As shown before, it is very hard to state definitely the bacteria which are the true etiological factors in a given case. Even if the source of "entry" is exactly found it is doubtful whether the organism in the joint is the same as in the "focus," as the organism changes under different environments. It is therefore absolutely wothless to give vaccines; perhaps even harmful. Some have injected non-specific protein antigen with the idea that the proteins of the bacteria are responsible for the cures. Those cases which I have observed following all forms and kinds of vaccine injection have turned out badly, and I have therefore abstained from using them.

If one has the facilities he may try to inject pus from the glands draining the joint into a rabbit. If the animal develops the same arthritis as the patient, a vaccine may be made and used. I have not had enough experience with that.

Local Treatment.—(*a*) Immobilization: As you probably know, the pain in the acute joints is very severe. In these cases, the general practitioner resorts to rubbing with different ointments. In our experience we found this to be entirely wrong. The reverse is advisable. (Use the same principle as in acute pleurisy.) As soon as the patient complains of pain, the joint should be immobilized in a well-padded circular plaster cast. Of course the plaster should not be too tight. The position of the joint should be properly selected; for instance, the knee must be kept in extended position, the ankle at right angle, the elbow flexed, and the wrist slightly hyperextended. The plaster application in many cases

works wonders. I can recall scores of patients in whom nothing could relieve the pain, but when the plaster was applied they found relief immediately or fell into gentle sleep. There is no danger that the joint will become ankylosed. Not the plaster but the rubbing and irritation of the forcible motion, as produced by the application of ointments, favor ankylosis. The plaster should be left on for only eight or ten days and then it should be split into two halves. The plaster is then left on during the night and only part of the day, being removed during the application of other local measures. The duration of the wearing of the plaster is gradually shortened. Of course where the pressure of pus is suspected in the joint and marked fluctuation is present, aspiration should be done.

(*b*) Medicinal Application: Ichthyol or antiphlogistin is absolutely valueless. There is no specific medicine to apply locally. For psychic (and to some extent real) effects we sometimes apply for the night the following: Tincture belladonna 15, tincture of aconite 15, crude oil ad 100.

(*c*) Active Hyperemia or Hot Dry Air is of great benefit. The methods by which active hyperemia can easily be produced in every house are bathing alternately in hot and cold buckets full of water, or applying a compress wrung out in hot water for five minutes and then a cold compress for five minutes. Bathing the limb in hot water with Epsom salt, about a quarter of a pound to a basin of water, is still better. We are not prepared to state the reason of the beneficial effects of Epsom salt, but it has a decidedly good influence, better than plain hot water or sea salt. If the skin is itchy, sodium bicarbonate may be added. The bathing may be done three or four times a day. The baking, or what is called "the superheated dry air method," is of course better, but here we found the greatest abuse as very few employ this method properly and efficiently. It should be used after the plaster bandage has been cut so that it can be opened. The temperature of the machine must be brought up gradually to 250° or 300° F. and the application should be given for three-quarters of an hour. Electrically heated apparatus are the best. At present they can be rented and used easily at the bedside. Do not put the bare limb into the machine but wrap it up at first in blankets (children's blankets are the best). Prolonged and gradual heat is the most efficacious. The baking by "electric light" is not as beneficial as that by the baking apparatus. The heat given by the lamps can be brought up only to 110° and cannot be continued for more than fifteen minutes. The frequency of baking during the acute attack is every day, later on only three times a week. Electric light baths may be used once a week, but the apparatus is expensive and only an institution like ours can afford such a luxury. Steam or hot air boxes have been used in our institution with good effects. The patient should stay there only ten minutes. The temperature should be 110° to 120° F. Diathermia has lately been introduced but we have not had enough experience with that.

(*d*) Bier's Passive Hyperemia, produced by means of a thin elastic bandage, is also of benefit. One must however know how to apply it. The constriction must be very slight, just enough to cause a narrowing of the superficial veins, but not an entire obstruction. The application can easily be taught to the patients, even in cases of feeble old women. This application is painful during the acute attack if it is not applied correctly, and should be used with care. It ameliorates the pain and the spasm. Begin to use it for two or three hours a day, increase gradually, till finally it can be left on for twenty-two hours daily, taking it off for one hour twice a day when the limb is to be raised to allow the return of circulation.

(*e*) Massage: This is of the greatest value if it can be carried out properly. It is that part of the treatment most commonly abused and perhaps also the one responsible for many disabling deformities. (I well remember many cases where members of the family were ordered to massage for four hours a day, and they had to take turns as they got tired. The massage was administered by the strongest men in the family. No massage should be used as long as there is still redness, tenderness, or signs of inflammation. In general we found that in the acute cases it takes from about four to six weeks before massage can be begun. When massage is to be used, it should be given by trained masseuses and not by osteopaths, chiropractics, or members of the family. It requires more skill to give proper massage to an acute joint than to any other ailment. As a matter of fact the first few massages are only of an experimental nature to see whether the patient will tolerate them or not. If he gets worse they must be discontinued. In my personal opinion, no man masseur should be trusted with a case of acute polyarthritis.* We have noticed many times that when a new masseuse was put in charge the patient complained of pain after the massage. Many of our patients improved under our gentle massage when they felt worse while being treated by the inexperienced masseuses. The massage should be given only three or four times a week in the acute cases. For chronic cases five times a week may be permitted. The massage should be given mostly to the muscles and not much to the joint itself. The forms of massage to be used are effleurage and slight friction. The muscles farther away from the joint can be treated by peterissage, *i.e.* kneading. The massage should always be given after the hyperemia, *i.e.*, after the bathing or baking. The duration of the massage should be 10 to 15 minutes on a joint. If several joints are to be treated, half of the time is sufficient. In hospital cases, general massage, and particularly abdominal massage, should be added to improve the disorders of the intestinal tract. It is not necessary to use any lubricant on the joint, ordinary talcum powder is sufficient. In the atrophic form of polyarthritis, massage can be practiced directly upon the joints as well as upon the muscles in the neighborhood without risk of stirring up any active process.

(*f*) Exercises: Active exercises are of great value. As soon as inflammation begins to subside, have the patient himself go through the normal range of motion of the joint two or three times a day and perform each motion about five times. The patient may be assisted only by arranging some pillows so as to help the motion by gravity.

* Prof. Tyrnauer of Carlsbad, the inventor of the baking machines, discussed this paper and remarked that in his clinic only physicians experienced in massage are allowed to massage such cases.

Passive exercises may be used in the chronic cases. At Montefiore we have elaborate and expensive Zander machines. We used them extensively. But of late we have begun to make use of occupational therapy, *i.e.* teaching the patient some trade or working with real tools, and choosing the exercises useful for him in each trade, and thus more interesting than merely mechanical exercises. We found this quite superior to the use of the Zander machines. A patient hates to sit and wiggle a stationary bicycle while he will work conscientiously and intelligently with a sewing machine or a saw, or chop wood.

(*g*) Hydrotherapy has been used from time immemorial and is certainly of actual benefit, but it is not advisable to depend entirely upon these means and send patients away to spas.

(*h*) Electrical treatments of all forms and derivations are valueless and some even harmful.

Prevention of deformities should be the main aim of the general practitioner. Steady the joints in the best position during the acute stage and many patients will be saved from permanent crippledom.

The discussion of correction of deformities and operative means does not lie within the scope of this article and I shall therefore omit it.

Conclusions.—1. The disease has no relation at all to rheumatism and antirheumatics should be avoided.

2. A focus of infection should be looked for in every case of arthritis where tuberculosis, malignancy, or trauma is not self-evident. The finding of one focus does not mean that this is the only one. The source of infection suspected should be removed if possible.

3. A monoarticular arthritis demands the same careful investigation as does a case of polyarthritis, for one can never tell when the former may merge into the latter.

4. Prophylaxis in preventing any systemic infection and keeping the genitourinary and intestinal tracts in good condition is essential. Removal of chronic foci anywhere in the body is imperative as a prevention of progressive ill health.

5. The arrest of infection does not mean that the joint will be cured, unless orthopedic measures are employed.

6. General treatment, such as good hygiene, good food, tonics, and building up of the patient, is essential to success.

7. Acute joints should be put in well-padded plaster casts for rest.

8. When active symptoms subside, local treatment to the joints, in the form of active and passive hyperemia, hydrotherapy, massage, active and passive exercises, should be administered regularly with great care and patience and kept up for a long time.

9. The occurrence of deformities should be prevented by steadying the joints in proper position at the time of the acute infection.

I shall give a few illustrative cases of Infectious Polyarthritis.*

CASE I.—Max G., male, married, age 40, came under observation in March, 1916, with a history of pain and swelling of left foot of two weeks' duration. Pain was not relieved by any medication used. Physical examination showed swelling of the left ankle and right knee. Temperature 100°. Murmur at apex of the heart. Marked pyorrhea alveolaris; enlarged tonsils.

A plaster cast was applied to the ankle and knee. This stopped the pain, but the temperature continued for a few days. Local treatment was applied to the tonsils and the dentist attended to his teeth, removing only one tooth. General treatment in form of diuretics and laxatives. The patient was feeling better, but the temperature continued for two weeks, coming down to normal only after the use of enemas. The plaster casts were removed after twelve days and baking was begun. Massage was begun one week later. The patient was discharged in May (ten weeks from the beginning) entirely cured. The last report from him in September, 1919, was that his joints had never troubled him since, but he has been suffering from marked endocarditis and has not been able to work on account of that.

Comment: What was the infection due to? The pyorrhea alveolaris, the tonsils or the intestinal tract? In view of the marked endocarditis one is bound to attribute this infection to the tonsils though the pyorrhea alveolaris and the intestinal tract played a very considerable rôle. The immediate improvement after the application of the plaster casts was remarkable.

CASE II.—David L., male, age 30, came under observation in April, 1917. Has always enjoyed good health. Denies gonorrhea and syphilis. Disease began five weeks before, with temperature of 101° F. and pain in both shoulders and knees. No redness, no swelling. Diagnosis of "rheumatism" was made by his attending physicians and the patient was saturated with antirheumatics and vaccines. Vigorous massage for four hours daily was also used, but no relief was obtained. On the contrary almost all the joints became involved. Had severe pain at night.

Physical examination shows both shoulders markedly swollen and tender, with limitation of motion in all directions. Marked stiffness of cervical spine. Right wrist markedly swollen. Some swelling of the ankle joints and slight swelling of the knees. Tonsils markedly enlarged. Teeth in good condition.

A plaster cast was applied to the wrist, baking to the other joints, bathing in hot water with Epsom salt, injections of sodium cacodylate, and internally iron, strychnine, and arsenic. I referred patient to a laryngologist, who began with local treatment to the tonsils.

The pain in the wrist stopped immediately. The improvement in the other joints was very slow. In three weeks the patient could use the shoulders much better than before, though he still had limited motion. Pain considerably lessened during the day; no pain at night. Not being satisfied with the improvement, I suggested removal of the tonsils, which was done. One tonsil had many adhesions and bled profusely. The patient improved very rapidly after that, and was discharged entirely cured after three months, but was still going to the laryngologist. At the last report in October, 1919, the patient was enjoying good health.

Comment: The fallacy of the antirheumatics and the value of the plaster cast is clearly shown. The infection was undoubtedly due to the tonsils.

CASE III.—Abraham A., age 28, male, married, came under observation in October, 1917. The previous history was negative. He has two healthy children. The present illness dates back fourteen weeks with pain in all the joints and swelling in several joints. He says he always has fever, though he has not taken the temperature with a thermometer. Had been treated with medication and vaccines but without relief; is getting worse all the time. *Physical* examination showed marked tenderness and swelling of both ankles and the right wrist, slight swelling of both knees. The shoulders and elbows show limited motion in all directions. The spine cannot be flexed freely. The tonsils are markedly enlarged. There is marked pyorrhea alveolaris. The tongue is coated. Temperature 101° F. I applied plaster casts to the right ankle and left

* These cases are taken from private practice as they will illustrate certain phases of interest to the general practitioner.

wrist. Enemas daily. Local application of hot water with Epsom salt. Injections of sodium cacodylate. Some local application to the tonsils. The pain in the joints with the plaster casts diminished markedly. The temperature, however, went up to 104°-105° F. with chills. The patient felt uncomfortable. I then ordered high colonic irrigations, purgatives, and diuretics. For the joints bathing in hot water with Epsom salt *t.i.d.* The plaster was not removed from the joints, but on the contrary another joint put in plaster. Attention was given to the teeth and tonsils. After a few days the temperature came down. The tonsils improved. Pain in the joints was considerably less. I then opened the casts and ordered bakisg. In two weeks I ordered massage, and in three weeks exercises. The tonsils were later removed and a few teeth were extracted. The patient was discharged entirely cured in five months. At the last report in January, 1920, the patient stated that he had never had any trouble since.

Comment: The history of an infection was clearly present in this patient, still he was treated for fourteen weeks for rheumatism. The tonsils, the teeth, and the intestinal tract were undoubtedly responsible for the arthritis. The improvement after the plaster was marked. The massage and the exercises had to be delayed for a long time.

CASE IV.—Mark W. C., male, letter carrier, single. Came under observation in May, 1916. He gave a history of malaria and gonorrhea, but the Wassermann has been negative on repeated examinations. The present illness dates back five weeks with swelling and pain in the ankles, knees, and hands, getting worse in spite of the antirheumatics. Examination shows both ankles, knees, wrists, and shoulders involved. The patient has very bad tonsils, and has been treated for some time for that and for ethmoidal sinusitis. Teeth in good condition. Under baking, massage, and the general treatment previously outlined, the patient improved immensely and was able to return to work after three months, though still in charge of the laryngologist. In a few months he had a recurrence of the attack affecting both knees and hands. Local treatment was resumed. Vaccines were used by the laryngologist. Improved after a few weeks.

During 1917 he had several attacks. The intestinal tract is in bad condition, and he is usually constipated. Attention to this by medication, diet, and exercises relieved the condition somewhat. During 1918 he again had trouble in the hands. The patient was then admitted to a general hospital where every available examination was made; he was kept under observation about four weeks, but no source of infection was found. The only possible cause was considered the tonsils. They were removed. While in general the patient feels fine, he has recurrent attacks of arthritis and cannot follow his occupation of letter carrier.

Comment: This case illustrates clearly how hard it sometimes is to find the focus of infection. The spread of infection has apparently been checked in this patient but a permanent cure has not been obtained.

529 COURTLANDT AVENUE.

THE VALUE OF IMMUNIZING DOSES OF INFLUENZA VACCINE IN THE PROPHYLAXIS AND SPECIFIC TREATMENT OF INFLUENZA.

BY WILLIAM EDWARD FITCH, M.D.,

NEW YORK.

NATURAL science had its beginning in experimentation. The successful research worker is a ceaseless painstaking observer. He theorizes, speculates, and formulates experiments to verify his hypotheses. Experimentation is the basic essence of our scientific knowledge.

All true investigators realize that it is no easy matter to plan and carry out an experiment to a successful termination. Even in the simpler physical sciences the elimination of disconcerting factors is not always a simple matter. In the biological sciences, more particularly in human medicine, conditions are so complex and the multiplicity of factors so great, that the study of any particular factor is often fraught with almost insuperable difficulties. Any one who will take the trouble to review the history of the many attempts during the past two or three decades to bring out and perfect specific serums and vaccines will find recorded countless wrecks of well meant endeavor and patient industry. Notwithstanding the failures of the past which lie wrecked on the rough rocks of fate, we must not for a moment slacken our effort or allow our enthusiasm to abate. The success already attained by our painstaking research workers in the prophylaxis and treatment of several infectious diseases should stimulate us to greater efforts, to fresh trials, and to experiments yet untried.

The success of Biological Therapy during the past few years is beyond question the greatest achievement which adorns the radiant pages in Modern Medicine of to-day. Scientific research has made possible the clearer understanding of the causes and effects of disease, as well as the means used by Nature to enable man and animals to recuperate from and give prophylaxis against disease.

The first step in this direction was the discovery of the important fact that each infectious disease is produced by a definite, specific bacterial infectious agent. It is also a proven fact that bacteria produce disease and cause death (*a*) by propagation within the tissues and fluids of the body producing either a local or a general bacteriemia with constitutional changes; or (*b*) by causing a local infection from which is liberated poisonous toxins—such as diphtheria and tetanus toxin.

The second step in this study was the application of Nature's laws in protecting the body against disease. Researches were undertaken to ascertain the reason why some individuals recover from and resist disease while others succumb and die. It was learned through painstaking research that the protecting immunity was due to certain immune bodies; and that these immune bodies, or antibodies, had the power of neutralizing and destroying the infectious agent. It was also ascertained that when a specific germ gained entrance into the body and set up a focus of infection the body cells were at once stimulated to action to repel the invasion and at once begin the production of a protective substance or antibody, which if produced in sufficient quantity would repel the invasion and stamp out the infection, but if in insufficient quantity the invasion is not repulsed and the infection increases, leading to ultimate death.

The recent pandemic of influenza which swept over this country and the rest of the world has been the subject of serious investigation to a surprising extent, not only because of its widespread prevalence, its alarming character, and grave mortality, but also because of its appearance during the great war, and its study by the medical depart-

ments of the armies of the world, including our own.

The exact etiology of influenza is still subjudice. From the present status of our knowledge of the bacteriology of influenza it is seriously questioned if Pfeiffer's bacillus, the *B. influenzæ* first described and isolated in 1892, has any etiological significance in this condition. Many eminent bacteriologists, including Victor C. Vaughan, Ludwig Hektoen, and other well known authorities, consider it a disease of "unknown origin."

Bloomfield and Harrop of Johns Hopkins University conclude from their studies of the recent pandemic of influenza that it was clinically identical with the epidemic in previous years. They emphasize the point, however, that there is no proof available to show that the Pfeiffer bacillus is the causative agent in uncomplicated influenza. Howard, also of the Johns Hopkins University, agrees with the last mentioned authors and practically all American investigators that the Pfeiffer bacillus is a secondary invader. W. H. Park, director of the Laboratories of the New York City Board of Health, avers that the microorganism causing this disease has not yet been identified.

Two prominent features stand out, sentinel like, indicating the action of a powerful toxin in influenza: (*a*) the consistent leucopenia and (*b*) the rapidity of onset with extreme prostration. Major McConnell, M.C., U.S.A. (*Jour. A.M.A.*, vol. lxxii, p. 1457) reviews the literature of various authorities and states that the blood counts taken early after the initial symptoms exhibit a striking leucopenia as low as 1,800 and averaging from 3,000 to 4,000. Brem, Bolling and Casper (*ibid.* vol. lxxi, p. 2138) in analyzing the pandemic of influenza at Camp Fremont, state that in the influenzal stage leucopenia was practically always present, and the average count was 6,000. Since it is a mooted question as to the exact etiology the search for the toxin has been more or less along empiric lines. Park reviews (*ibid.* vol. lxxi p. 476) his most interesting studies of the etiology of the recent pandemic of influenza and concludes that the organism produces a substance of great toxicity.

The mortality of the recent world-wide pandemic of influenza has taken by far a greater toll of American life than has the great war. The Bureau of the Census showed that for a period of sixty days—from Sept. 8 to Nov. 9 inclusive—in 46 large cities with an estimated population of 23,000,000, there was a mortality of 86,306 deaths from influenza. The total casualties in the American Expeditionary Forces has been unofficially estimated to be 100,000 and the deaths from influenza alone to be from 40,000 to 45,000. Thus in the 46 American cities with a combined population of a little less than one-fifth of the total for the whole country, the mortality due to influenza in a short period of time was nearly double that of the American Expeditionary Forces in France.

Rosenow, of the Mayo Clinic, Rochester, Minn., in a paper in the *J. A. M. A.*, vol. lxxii, No. 1, p. 31, discusses his experiences with the treatment of influenza and emphasizes the value of prophylactic inoculations in the successful treatment of the disease. He cautions that we put aside the much debated question of the specific cause of the initial symptoms, and strongly urges the early immunization of persons against the bacteria of pneumonia, streptococci, staphylococci, and the influenza bacillus—which are conceded to be the cause of death in this disease. Rosenow and his associates made an influenza vaccine containing the following: pneumococci types I, II, III, and pneumococci group IV, strains of hemolytic streptococci, staphylococci, and the influenza bacillus. All of the physicians, nurses, and employees of the several hospitals were first inoculated, and the vaccine was furnished gratis to all physicians within 200 miles of Rochester. Rosenow states that all but two of the 70 physicians to whom he sent vaccine reported that the attacks of influenza if contracted after inoculation were milder and of shorter duration and that convalescence was more rapid than in the uninoculated. In one of the Rochester hospitals in which all of the nurses were inoculated, not a single case developed among the nursing staff, although they continued on duty nursing influenza patients.

Rosenow's initial dose of vaccine for adults was 0.5 c.c. administered subcutaneously. One week later the second dose of 1 c.c. was administered, and the third dose of 1.5 c.c. was given 14 days after the first. The dosage for children ranged from 0.1 to 0.3 c.c. according to age. A moderate reaction was noted. The constitutional symptoms were very mild or altogether absent.

A number of competent clinicians have reported most favorable results from the use of immunizing doses of vaccine in the prophylaxis and specific treatment of influenza. Others report excellent results from the administration of vaccines in minute doses of 20 million organisms during the febrile stage of the disease.

Another notable advance in the specific treatment of this disease has been the injection of the serum from a convalescent patient into the circulation of a patient suffering from the disease, when due to the same organism. McLean and Pepper report very satisfactory results from the administration of convalescent serum to influenza patients.

Eyre and Lowe, writing in the *Lancet*, April 5, 1919, present their combined clinical results among the New Zealand troops from the administration subcutaneously of a vaccine as a prophylactic measure against influenza. The vaccine used was polyvalent containing many strains of pneumococcus, streptococcus, staphylococcus, and the influenza bacillus. Of a total of 21,759 men in the garrison, 16,104 were given two doses at ten-day intervals and 5,700 received only one dose. The total strength of the garrison was 21,759 men, of whom 15 per cent. came down with the disease, but the infective incidence in the fully inoculated was only one-third that in the partially or uninoculated. The mortality in the uninoculated was three times as great as in the inoculated for the severe cases, while the total for all cases infected was nine times as great in the former as in the latter.

In October, 1918, the physician to the Philadelphia Electric Co. administered immunizing doses of influenza vaccine to the 4,000 employees of the company with the brilliant result of only three men contracting influenza. Prof. Solomon Solis Cohen of Philadelphia states that the mixed bacterial vaccines are as valuable and efficient in the treatment and prophylaxis of influenza and its complications

as mercury is in syphilis or quinine in malaria.

William E. Robertson has administered intravenously the mixed vaccine in hundreds of cases of influenza in various stages of the disease and has been rewarded with the most satisfactory results. Thousands of soldiers were successfully inoculated at the various army cantonments, escaping the disease, and many thousand citizens of New York City, Boston, Chicago, Philadelphia and other places received prophylactic immunization and were thereby saved from serious illness, or perhaps death.

There is no danger from administering the prophylactic immunization during an epidemic, or even giving the vaccine to a patient who later turns out to be in the incubation period at the time of injection. This prophylactic immunization is of decided value, not only in reducing the incidence of the disease, but also in diminishing its severity in those who are attacked in spite of its administration.

405 LEXINGTON AVENUE.

THE BLOOD IN INFLUENZA.

BY B. LEMCHEN, M.D.,

CHICAGO, ILL.

PHYSICIAN TO THE CHICAGO STATE HOSPITAL.

THIS paper represents examinations of blood of some of those that were sick with influenza during the months of January and February, 1920, including 14 unselected cases out of 115 patients and employees treated at my service at the Chicago State Hospital.

CASE I.—Mr. M. Total leucocytes, 3,000; polymorphynuclear, 41%; small lymphocytes, 1%; large lymphocytes, 2%; large mononuclear, 37%; esinophiles, 2%; transitionals, 13%; unclassified, 4%.

CASE II.—Mr. T. Total leucocytes, 5,000; polymorphynuclear, 63%; small lymphocytes, 15%; large lymphocytes, 9%; large mononuclear, 2%; transitional, 7%; unclassified, 4%.

CASE III.—Miss L. Total leucocytes, 4,300; polymorphynuclear, 14%; small lymphocytes, 43%; large lymphocytes, 31%; large mononuclear, 3%; transitional, 8%; unclassified, 1%.

CASE IV.—Mrs. B. Total leucocytes, 9,600; polymorphynuclear, 17%; small lymphocytes, 14%; large lymphocytes, 6%; large mononuclear, 32%; esinophiles, 3%; transitional, 6%; unclassified, 22%.

CASE V.—Mr. D. Total leucocytes, 12,000; polymorphynuclear, 77%; small lymphocytes, 9%; large mononuclear, 13%; unclassified, 1%.

CASE VI.—Mr. A. Total leucocytes, 7,200; polymorphynuclear, 77%; small lymphocytes, 17%; large lymphocytes, 1%; large mononuclear, 4%; esinophiles, 1%.

CASE VII.—Miss R. Total leucocytes, 6,000; polymorphynuclear, 48%; small lymphocytes, 25%; large lymphocytes, 13%; large mononuclear, 8%; transitional, 3%; unclassified, 3%.

CASE VIII.—Miss W. Total leucocytes, 6,400; polymorphynuclear, 70%; small lymphocytes, 1%; large lymphocytes, 4%; large mononuclear, 20%; transitional, 3%; unclassified, 2%.

CASE IX.—Mrs. H. Total leucocytes, 11,800; polymorphynuclear, 77%; small lymphocytes, 3%; large lymphocytes, 1%; large mononuclear, 12%; transitional, 5%; unclassified, 2%.

CASE X.—Mr. G. Total leucocytes, 17,800; polymorphynuclear, 78%; small lymphocytes, 10%; large lymphocytes, 2%; large mononuclear, 3%; esinophiles, 1%; transitional, 1%; unclassified, 5%.

CASE XI.—Mrs. D. Total leucocytes, 8,600; polymorphynuclear, 61%; small lymphocytes, 13%; large lymphocytes, 8%; large mononuclear, 2%; esinophiles, 1%; transitional, 5%; unclassified, 10%.

CASE XII.—Mrs. B. Total leucocytes, 6,000; polymorphynuclear, 20%; small lymphocytes, 15%; large lymphocytes, 6%; large mononuclear, 36%; transitional, 6%; unclassified, 17%.

CASE XIII.—Miss D. Total leucocytes, 5,200; polymorphynuclear, 61%; small lymphocytes, 14%; large lymphocytes, 7%; large mononuclear, 15%; esinophiles, 1%; transitional, 2%.

CASE XIV.—Miss G. Total leucocytes, 2,800; polymorphynuclear, 46%; small lymphocytes, 39%; large lymphocytes, 6%; large mononuclear, 7%; transitional, 1%; unclassified, 1%.

In all cases studied there was also a great diminution of blood platelets, with an increase of the coagulability of the blood. In some of the patients the blood would coagulate while I drew the blood and the acetic acid in the pipet, which would take me from one to two minutes, and for making smears I would have to prick the finger again. Case V had in addition a tonsillar abscess. Case IX developed purpura hemorrhagica, case XI otitis-media, case IV and case XII broncho pneumonia. Two cases not in this series have developed empyema. In one I found the streptococcus and in the other the pneumococcus.

Nine out of this series had uncomplicated influenza and all had a persistent leucopenia, with a great decrease in the polymorphonuclear elements, with the platelets and an increase in the viscosity of the plasma.

It soon appeared to me that the virus of influenza early in the disease enters the blood stream, attacks the polymorphonuclear leucocytes with blood platelets, and these, during their destruction, liberate something, probably a ferment that increases the viscosity of the blood, which hastens its coagulability. For the same reason the host inhibits the rapid formation of the polymorphonuclear lucocytes, as in the majority of the infectious diseases, so as not to increase still more the viscosity of the blood, and for this reason we find the persistent leucopenia. That prostration, apparently due to the increase of the viscosity of the blood and the diminution of the defenders, polymorphonuclear leucocytes, in a person suffering from influenza, will predispose him to the so many complications and especially respiratory complication, would surprise no one. To counteract this we must try to diminish the coagulability of the blood. For this reason I pushed fruits that contain citrates. As I believe I received good results, I would like to outline my plan of treatment.

When a patient was received at the hospital department and a diagnosis of influenza was made, and there were no counter indications, I gave him calomel, gr. 1/10, every 15 minutes. Two hours after the last dose of calomel I gave Epsom salts, ℥ i in water. The first day the patient was allowed nothing but water, after small amounts of milk, cooked cereals, soft-boiled eggs, soups, first in small quantities, watched which food best agreed with the patient, then I would increase it. Milk, owing to its large amount of calcium salt, was given as little as possible. From the fruits that contain citrates I first tried lemons in the form of lemonade, but for some reason my patients did not stand lemonade well, as they would vomit soon after taking it. Then I gave orange juice, which was well retained. However, I found that grape fruit sweetened with sugar was better retained than any others and I pushed it. Occasionally I used potassium citrate,

but only occasionally. In a few instances I used also digitalis, aspirin and Dovers powders. In the majority of the cases I relied entirely on the grape fruit.

I treated in all 115 cases and lost 10 cases, which would seem high, but considering the kind of cases, I believe the result was very satisfactory. Several of those that died were in the later stages of general paralysis of the insane, others were of the senile type and difficulty of carrying out treatments among the insane.

Only one of those that died was under 40 years of age and none of the employees died. On the same reasoning it appears to me that when we succeed in isolating the organism that causes influenza, a vaccine of it, together with citrates, ought to prove of value in myologenous leucemia. As pernicious anemia is apparently due to decrease in the viscosity of the blood, a vaccine of the same organism, together with sodium nuclenate, that stimulates the formation of leucocytes, ought to prove of value.

CANCER OF THE OMENTUM.

By J. N. STUDY, M.D.,

CAMBRIDGE CITY, IND.

On February 26, 1919, I visited Caroline J——, age 76 years. In my examination my attention was attracted to an enlargement in the right side of the abdomen extending from the lower border of the liver downward toward the lower part of the abdominal cavity. This enlargement was quite movable, unattended with pain, somewhat flattened on the surface, and rather hard and somewhat oval in shape. There had been some previous noticeable loss of flesh.

I visited the patient at intervals until her death, September 16, 1919. There had been a continued gradual loss of flesh, without pain or other bodily disturbance. The tumor became larger and remained quite movable until her death. Necropsy findings were a growth, flat on the external surface, somewhat ovoid in shape, about six inches long, estimated weight two and one-half pounds, occupying the right side of abdominal cavity and extending over the median line to the left one and one-half inches. This tumor was quite movable and not attached to any organ and was of hard consistency. The gross appearance was cancer of the greater omentum, which section plainly indicated.

For more accurate statistical facts for reporting, the writer throughout his professional career as a general practitioner of medicine for many years, seldom has missed an opportunity to make autopsies in obscure and doubtful cases, some of which have proven to be very interesting. In a particular instance the gross appearance indicated cancer of the lungs, and the specimen was verified as cancer under the microscope by the late Dr. E. G. Janeway of New York.

Through the courtesy of F. L. Hoffman, statistician for the Prudential Life Insurance Company of America and author of "Mortality from Cancer Throughout the World," some statistics concerning the comparative frequency of cancer of the omentum are appended.

Galen's Digestive Pathology.—Galen knew of stricture of the esophagus in different degrees and from different causes, and knew that bones, etc., lodged in this canal could set up abscesses. He knew also of distention and dilatation in pockets and vomiting of blood from trauma and ulcer. Headache was often due to the stomach and in some subjects a little wine was sufficient to cause it. Sour stomach, water brash, salivation, eructation, etc., were symptoms of a common condition—acid stomach with glairy catarrh. Boulimia, abnormal cravings, etc., were well known in his day.—*Journal de Médecine de Paris.*

New York, July 17, 1920.

THE HYPERGLYCEMIC REACTION.

ABOUT a year ago we had occasion to call attention in these columns (MEDICAL RECORD, August 23, 1919) to the changes that occur in the glucose content of the blood following the ingestion of glucose or the injection of adrenalin. At that time it was recognized that a definite hyperglycemic reaction occurred in a number of diverse conditions and we took the opportunity to point out the improbability of there being a sound basis for a test then proposed for the detection of malignancy founded upon a reaction of a certain type. During the past year many interesting studies have been carried out in an attempt to determine the nature of this reaction and the factors which control it. There are two which have especially attracted our attention and which deserve comment.

Jacobsen and Edwards have been investigating the influence of protein meals in diabetics and nephritics and report some interesting observations (*Am. Jour. Med. Sci.*, clix, 833, June, 1920). The standard meal used consisted of fifty grams of protein in the form of beefsteak and 200 c.c. of water. The blood was examined before and at varying intervals up to twenty-four hours after the meal. The plasma sugar of normal persons was not appreciably affected by this meal, but in cases of diabetes which were sufficiently severe there was a definite hyperglycemic reaction. The authors are of the opinion that this procedure may be of some value in determining the degree of severity of a case of diabetes. They found also that a similar reaction was apt to occur in cases of nephritis. There has been much discussion as to the nature of the substance which gives rise to high blood sugar values in nephritis. It reacts in a similar manner in all of the methods used and possibly may be glucose, but most of the chemists who have worked on the problem are inclined to think that it is some other substance which reacts like glucose both to copper salts and to picric acid. The question is still being actively investigated.

Rohdenburg and Pohlman have studied another phase of the subject. They injected rats and rabbits with a large number of different substances and studied the sugar content of the blood at fixed periods thereafter (*Am. Jour. Med. Sci.*, clix, 853, June, 1920). They found that one of three types of reaction occurred after the injection of various organic and inorganic preparations and that the reaction was not influenced by the removal from the animal of any of the glands of internal secretion. No reaction type was specific for any of the substances injected. They are of the opinion that a reaction induced by so many different agents must of necessity play a most important part in the physiological and pathological processes of the organism. Indeed, if appears to be one of the manifestations of disturbance of the normal balance which exists between the different members of the endocrine system. But the significance of a reaction that occurs with such frequency can be estimated only with the greatest difficulty if at all. The greatest caution must be used in applying it to the solution of any problem.

These authors found that when the substance injected was typhoid vaccine repeated injections were accompanied by a gradual rise in the blood sugar parallel with the rise in agglutinins or lysins, and that when the agglutination titer had reached its maximum, no further glycemic reaction occurred. This observation is made for the first time and naturally cannot yet be explained. Confirmation must be had of the author's results and much investigation must be carried out before it would be permissible even to speculate on the question. If their observations are confirmed it may be possible, as they suggest, to use this fact to determine when an immunization has reached its highest point, or it may be used to study the reaction of the body to such substances as glycerin, fats, etc., which do not call forth antibody production. The hyperglycemic reaction is, therefore, obviously one of great complexity and can be used at the present time only in the investigation of those conditions in which its variations have been sufficiently studied to permit us to draw reasonably safe conclusions. Beyond the one or two conditions in which these safeguards are present the interpretation of this reaction lies in the realm of pure speculation and reliance upon it is an unsafe procedure.

OBSTETRICS AND THE STATE.

THE most severe indictment of the methods of teachings midwifery in a civilized country was made recently by Dr. Comyus Berkeley, obstetric and gynecological surgeon to the Middlesex Hospital, London, in an address he gave in London and which was published in the Bulletin of the Fellowship of Medicine. He asserts that the present position of midwifery in the United Kingdom, from both the public and the professional point of view, is a disgrace. According to Berkeley the causes that have prevented any improvement in midwifery are threefold: (1) The lack of proper provision for the lying-in woman. (2) The superficial nature of the training of the student in midwifery. (3) The failure of the public to recognize the import-

ance of midwifery. In the *Canadian Medical Association Journal* for April, 1920, is a paper by Dr. K. C. McIlwraith of Toronto dealing with the same subject. From statistics quoted in this paper it appears that the mortality of childbirth is greater in the United States than in Great Britain, as in 1910 the total maternal mortality was 3.69 per 1,000 living births, of which 1.44 were due to sepsis, while in the registration area of the United States in 1910 the total rate was 6.5 per 1,000 living births with sepsis at 2.9, giving a proportion of 44 per cent. New York City probably brought the figures up that year by providing the enormous mortality of 10 per 1,000, with 5.7 or over 50 per cent. of the total due to sepsis. In Ontario during the years from 1909 to 1918 inclusive the figures furnished by the Registrar-General show a total mortality of 5.4 per 1,000 living births with sepsis accounting for 1.88 or a percentage of 35. Dr. Grace L. Meigs gives statistics of fifteen other countries and McIlwraith points out that in twelve countries of which the statistics have been analyzed, for the purpose of ascertaining what percentage of the total death-rate is due to sepsis, it has been shown to vary from 30 to 50 per cent. McIlwraith and other authorities believe that this death rate is nearly all preventible, and he draws attention to the fact that this is only one of the preventible causes.

The writer says that in his opinion the following are some of the causes of puerperal death in Canada: (1) Many years of observation have led him to the conclusion that some, at all events, of the morbidity and mortality in childbirth has resulted from meddlesome midwifery. There is too great a tendency to injudicious, and particularly to premature, use of forceps. Furthermore, an obstetrician is, by virtue of his specialty, a surgeon, and must exercise as much care in this branch of the work as is exercised in any other. Many men doing obstetric work in hospitals fail, McIlwraith is afraid, to realize the value of the precautions by which their work is there surrounded. The aseptic delivery room, sterilized water, solutions, dressings, instruments, and ligatures; the preparation of the patient for delivery, the gloves, gowns, caps, and masks, with which they are supplied, are taken for granted, laughed at, or even refused. McIlwraith thinks it likely that if called upon to reproduce these conditions in a private house, many would not know how, or would not take the trouble. (2) The public is grossly ignorant of the real danger of parturition, and is inclined to regard the effort of the careful obstetrician as mere ostentation. Among the better class of patients a great improvement has taken place, most people now demanding that supervision which they used to reject, but ignorance still persists among the poor. (3) Much obstetric surgery—instrumental deliveries, versions, repairs of the perineum—is undertaken in surroundings that make it unsafe. It is the venue of the case, the writer believes, quite as often as failure of mechanical skill on the physician's part, that leads to disaster. (4) One curious fact comes out in Sir Arthur Newsholme's report, that the mortality increases noticeably the further north we go, being lowest in the southern, higher in the midland, higher still in the northern countries of England, and highest of all in Scotland. Perhaps no great significance attaches to the fact but it is in accord with McIlwraith's observations on the effect of climate.

As for remedying the existing unsatisfactory state of affairs as regards the management of labor, two features stand out: first, that the training of medical students and of midwives must be more thorough in every respect, and second that better facilities must be provided for the great majority of women in labor. In this country the facilities provided for those who can afford to pay are excellent, with regard to both the skill of the obstetrician and the environment. But it is altogether a different matter with those whose means will not permit of their being placed in a lying-in institution. The question in every country is a national one, and in some countries the State is beginning to recognize it as such. In England, for instance, the Ministry of Health, a State bureau, realizes its responsibility in the matter and has given notice that the erection of maternity hospitals is a part of its program. The public is ignorant as to the dangers of midwifery and the profession has been and still is, to some extent, indifferent and lethargic. In no branch of surgery is reform more urgently called for than in that of obstetrics, and it is encouraging to know that the profession and intelligent citizens are becoming aware that such is the case.

SACROCOCCYGEAL INFUNDIBULA AND CONGENITAL PARACOCCYGEAL SINUSES.

THE clinical aspects and symptoms of sacrococcygeal infundibula and congenital paracoccygeal sinuses are not devoid of practical interest, especially in order to avoid mistaking these for other lesions which are met with in this region. A subject possessing one of these congenital defects may be completely unaware of its presence and consults the physician for some other affection, when the defect will be observed during examination. In some instances the physical symptoms will take the form of spontaneous or provoked pain over the coccygeal region. Spontaneous pain is uncommon, the patient being more liable to complain of a pricking sensation or pruritus, indications of an inflammatory process arising in or around the defect. At other times, on the contrary, shooting pain may be complained of, extending to the lumbar region, buttocks, or thighs. The pain occurs when the patient moves or indulges in violent exercise or after long walks.

By questioning, one will learn that the linen is spotted by a serous discharge, or it may be purulent, while inspection will give more definite data as to the extent and importance of the defects. Infundibula and foveolæ are met with in various forms, being circular, oval, or parabolic in shape.

There may be one or several depressions and it is essential to ascertain if these are seated in front of the coccyx, over its tip, over the sacrococcygeal joint, or still higher up in the sacral region. Note should be made of their situation in the middle line or to the sides. Inspection will also allow one to appreciate the difference of color and apparent structure of the skin around the defect, as well as the presence or absence of plication.

The study by simple inspection of a paracoccygeal sinus arising in congenital defects will result in obtaining important clinical data. What will sometimes strike one at first glance is the change observed in the color of the skin: the integuments of the region may offer a hyperemic or ecchymotic redness, but there is neither vascular dilatation, abnormal pigmentation, nor hypertrichosis. However, the usually narrow orifice, round and marked by folds on its surface, is commonly made up of normal skin which dips down into the track of the sinus. There may be numerous orifices, and the adventitious openings are reddish, indurated, and frequently fungous; in a word, they offer the usual appearance of any fistulous openings. The direction of the sinus in relation to the cutaneous surface—perpendicular or oblique, should be noted, as well as the nature of the discharge—serous or sometimes purulent, to which it gives exit. After these points have been examined, palpation should next be done. Some discharge may be expressed, purulent in nature and occasionally streaked with blood, coming from ruptured capillaries in the walls of the sinus. Occasionally there may be an elevation of the temperature, due to secondary infection or retention of the secretion, and when the amount of purulent fluid in the cavity is sufficient, fluctuation may be elicited, while some edema of the region is sometimes manifest. The extent of the mobility should be ascertained; in some cases it is diminished, in others completely absent. Pressure over the parts will cause some pain or discomfort. The regional lymphnodes are to be examined and will occasionally be found enlarged.

These congenital defects may be mistaken for either syphilitic or tuberculous lesions, but such a mistake in diagnosis will not be likely to occur if one recalls the clinical aspect of the condition and especially the fact that sacrococcygeal infundibula and congenital paracoccygeal sinuses are not so uncommon as has been generally supposed. The all-important fact to be remembered is that when these congenital paracoccygeal sinuses are explored with a probe, no denuded bone surface will ever be discovered, and this alone will differentiate them from the sinuses developing later in the region.

Recent Developments of Cardiovasculorenal Pathology in France.

In an issue of the new French journal, *La Médecine*, for March, 1920, i, 6, devoted exclusively to these affections, Ribierre sketches the recent contributions by Frenchmen in this field. By means of simple exploratory technique Josué and Laubry have been able to differentiate between structural and functional murmurs, while Vaquez has made contributions to our knowledge of functional valvular insufficiency. The results show the prevalence of error in some of the old teaching. The same school has introduced certain instruments of precision, such as the sphygmotensionmètre of Vaquez and the Vaquez-Laubry sphygmotensionphone; while the oscillomètre of Pachon is in common use. Pachon is himself a physiologist and the popularisation of his instrument is due largely to the efforts of Aubertin. Orthodiagraphy owes much to the labors of Vaquez and Bordet, Weill, Harvier, and Laubry. Graphics and especially electrocardiography have been pronounced by Vaquez absolutely necessary to establish the status of arrhythmias, and Routier has made the same resource necessary for auriculoventricular dissociation, etc. Josué has initiated auscultation of the venous pulse and viscosimetry of the blood. Coming to the subject of renal pathology the work of Widal, Weill, and Pasteur Vallery-Radot during the past fifteen years on the prognosis of chronic nephritis on the basis of the blood urea, etc., and that of Ambard in connection with the ureosecretory constant, to say nothing of the early work of Widal on chlorine retention and its dietetic treatment, are now common assets of medical practitioners everywhere.

Relations of the Cerebrum to the Sexual Functions.

Dr. Desogus, writing in *La Riforma Medica* for February 28, xxxvi, 9, claims for Professor Ceni the pioneer work on this subject. He originated a course of animal experiment along these lines and was able to point out that the nerve centers exercise a trophic action over the sexual apparatus. Destruction of parts of the anterior lobes of the brain in both higher and lower vertebrates is followed by involutional changes in the gonads. At the same time the sexual instinct is suppressed and the secondary sexual characters recede. But sometimes these changes are only temporary, especially in the older animals, while in the young animal they are apt to be progressive and accompanied by premature senescence. Under favorable conditions the losses which follow the operation are regained to a greater or less degree. Recovery may be very slow and incomplete. During the period of default the ovaries may be seen to be structurally altered and recovery of function coincides with restoration of the normal structure of the glands. There is great variation seen in individuals. These relations are upheld by finds in England on the ovaries of insane women and in Norway by the action of alcohol on the same glands. Similar is the relationship between the nervous centers and testicles. The changes seen in the male gonads in insanity are associated with spermatogenesis, the interstitial tissue increasing at the expense of the secretory apparatus, as is also seen in cryptorchism and after röntgenization and vasectomy. Elaborate work along these lines was published by Todde in 1911. Ceni insists that the connection between the brain and gonads is a direct one and not effected through any intermediary like the ductless glands.

Prognosis in Acute Nephritis.

In acute nephritis, according to Merkler, writing in *La Médecine* for March, 1920, i, 6, the prognosis does not depend on any one factor to the exclusion of others. Generally speaking the older the subject the worse the prognosis, for in the child repair is more readily effected by Nature. The virulence of the original disease which preceded the nephritis is a factor to be reckoned with. Thus in an unrecognized scarlatina the renal lesion may be slight although absence of the needed treatment is a factor which works in the opposite direction. A kidney already the seat of a lesion offers less resistance to an infection than an intact kidney. The coexistence of lesions of other emunctory organs aggravates the prognosis for obvious reasons. There is such a factor as hereditary renal weakness which has the same consequences, so that the family history may be useful. Albuminuria which does not diminish under rational treatment of the disease is unwelcome in prognosis and the same is true under analogous circumstances of edema and chloruremia and anuria. Depressive and inhibitory nervous symptoms foretell coma unless relieved, while motor excitement on the contrary, unless severe, is much less to be feared. Progressive digestive disorders are unfavorable, but respiratory symptoms such as renal asthma are less menacing. Hypertension is not the factor that one would suppose in prognosis save when rupture of a vessel is inevitable. Marked azotemia in acute cases is dangerous only when there is no tendency to recession in a short time.

Alleged Syphilitic Autosuperinfection.

The following case is reported in *La Medicina Ibera* (March 6, 1920, x, 122), by Fernandes de la Portilla of the San Juan de Dios Hospital, Madrid: A man, aged 23, entered the service of Dr. Sainz de Aja with a chancre cicatrix and secondary syphilis, the infection going back to ten months before admission. He received intensive treatment in the form of grey oil injections and for several months remained free from all evidences of the disease. A second chancre then appeared close to the first, both having been preputial, and this was followed by adenopathy, the provisional diagnosis being reinfection, with the possibility of superinfection. It was impossible to prove that the disease had been cured by the mere injection of grey oil not over four times in succession and the diagnosis of superinfection was substituted. The question narrowed down to auto- or heteroinfection and as coitus was vigorously denied and no evidence of exposure could be found the case was thenceforth regarded as one of autosuperinfection. The original chancre was doubtless not sterilized by the slight amount of treatment, although the spirochetes were perhaps brought to a state of latency and at a later period they appear to have become free at the periphery of the scar of the first sore and to have produced a second sore. The limit heretofore established for superinfection is much shorter than that in evidence in this case, and we dare say that in the judgment of the most expert syphilographers the lesion would be called a pseudochancre, of which there are numerous types. There is no mention of the Wassermann or microscopic control.

News of the Week.

Pan-Hellenic Congress of Hygiene and Demography.—Simultaneously with the celebration of the centenary of Greek independence, the first Pan-Hellenic Congress of Hygiene and Demography will be held at Athens April 25 to 30, 1921, under the presidency of Professor Phocos. Six sections will be represented: Public health, individual hygiene, military and naval hygiene, demography, infantile hygiene, and prophylactic hygiene. An international exhibition of hygiene and medical industry will be opened at the same time as the congress and will continue until June 25th. Further information concerning the congress and exhibition may be obtained from Dr. P. Rondopoulo, 14, Rue Nikiforon, Athens.

Far East Medical Education.—In the third installment of the report of the Rockefeller Foundation President George E. Vincent outlines the work last year of the China Medical Board, which seeks to aid the agencies which represent Western medicine in China to make steady progress toward higher standards and more efficient service. The chief agency, according to the report, by which it is hoped to further these aims is the Peking Union Medical College, recently opened and being completed. It is to have laboratories for anatomy, philology, and chemistry; a pathology building; a 250-bed hospital; a large out-patient department; quarters for resident physicians, nurses and internes; faculty residences; and its own light, heat and power plants. Three of the teaching buildings were occupied in October, 1919, and it is expected that the entire plant will be completed by January 1, 1921.

Bubonic Plague in Texas.—Eight cases of bubonic plague have been reported at Beaumont, Texas, by the State Health Officer. Three of the cases were fatal. Three cases with two deaths have been reported at Galveston. The State is waging a vigorous crusade against rats.

Commission of Medical Education Meets.—The first meeting of the Commission of Medical Education in Virginia was held June 28 at the capitol in Richmond. Dr. Wilbur C. Hall of Loudoun was elected chairman and Dr. Theodore Huff of Charlottesville was made secretary. The commission will make a thorough investigation of the present status and future possibilities of medical education in Virginia, especially as these relate to a merger of the Medical College of Virginia with the medical department of the University of Virginia. It was resolved that the press should be barred from the sessions.

Victory for Alabama Medical Association.—The Supreme Court of Alabama recently confirmed the decision of the Montgomery Circuit Court whereby the Alabama Medical Association will continue to name the State board of health and will continue to be the chief authority for the enforcement of all State laws relating to health.

Medical Internes Wanted.—The United States Civil Service Commission announces an open competitive examination, to be held October 1, for medical interne. Vacancies in Saint Elizabeth's Hospital, Washington, D. C., at $1200 a year and maintenance, and vacancies in positions requiring similar qualifications, at this or higher or lower

salaries, will be filled from this examination. Appointees whose services are satisfactory may be allowed the temporary increase granted by Congress of $20 a month. The positions are tenable for one year. During the year, however, a postgraduate course in mental and neurological diagnostic methods is given, an examination is held, and promotions to the next grade, junior assistant physician, are made. Beyond this there is regular advancement for employees whose services are satisfactory. Saint Elizabeth's Hospital has over 3,000 patients and about 800 employees to care for. In addition to the general medical practice offered, the scientific opportunities in neurology and psychiatry are unsurpassed. Both men and women, if qualified, may enter this examination. Applicants should apply for Form 1312, stating the title of the examination desired, to the Civil Service Commission, Washington, D. C., or to the secretary of the local United States Civil Service Board.

Bacteriologists Wanted.—The United States Civil Service Commission announces open competition examinations, to be held October 1, for bacteriologist and junior bacteriologist. Vacancies in the Public Health Service throughout the United States are to be filled from these examinations. The register of eligibles resulting from the bacteriologist examination will be used for filling vacancies in the positions of bacteriologist at $130 to $180 a month and associate bacteriologist at $90 to $130 a month. The register of eligibles resulting from the junior bacteriologist examination will be used for filling vacancies in the positions of assistant bacteriologist at $70 to $90 a month; junior bacteriologist at $70 a month; and junior bacteriologist, part time, at $30 to $50 a month. Appointees will be allowed subsistence, and one room or $15 to $20 a month in lieu of quarters, according to grade and station. Appointees whose services are satisfactory may be allowed the temporary increase granted by Congress of $20 a month. The entrance salary within the range stated will depend upon the qualifications of the appointee and the duty to which assignment is made. Applicants should apply for Form 1312, stating the title of the examination desired, to the Civil Service Commission, Washington, D. C., or to the Secretary of the local United States Civil Service Board.

New York State Civil Service Examinations.—Examinations will be held by the New York State Civil Service Commission, July 31, for the following positions: Assistant Medical Examiner, State Industrial Commission, salary $2000; Physician and Assistant Physician, State institutions, salary, $1,500 to $1,800 and maintenance; Physician (psychiatrist), Syracuse State School for Mental Defectives, salary $2,000 and maintenance. Request for further information should be made to the State Civil Commission, Albany, N. Y.

The British Medical Association, which has just held its annual session in Cambridge, will meet next year at Newcastle-on-Tyne and in 1922 in Glasgow. Dr. David Drummond, Vice-Chancellor and Professor of the Principles and Practice of Medicine at the University of Durham, has been elected president of the Association for 1921-22.

Crime May Bar Bay State Physicians from Practice.—The Attorney General of Massachusetts has recently ruled that a physician who is convicted of any crime may be barred from practice in that State, even though such crime is committed outside the practice of his profession.

Classes for Crippled Children.—The sum of $258,245 was requested for the classes for crippled children in the New York City public schools for 1921. This was reduced to $44,000, which was provided. The number of classes was reduced from the thirty-six requested to nine. Provision was made for five additional classes for children with speech defects in the elementary schools and for three additional classes in the high schools. A class in each of the training schools for teachers, for the instruction of prospective teachers for correction of speech defects, was allowed.

Chicago Doctors Form Union.—A movement has been started, according to Dr. Thomas P. Foley, chairman of the contract practice committee of the Chicago Medical Society, to organize a union among the members of that body which will correspond to the lawyer's association and other such organizations of professional men. It is said not to be aimed at the public, but rather at industrial and other corporation employers of physicians to force them to increase salary scales for regularly employed physicians and surgeons.

Funeral of General Gorgas.—The funeral of Major-General William C. Gorgas, who died in London, July 4, was held in St. Paul's Cathedral at noon on July 9, with military honors. The pallbearers included the Military and Naval Attachés of the American Embassy; the President of the Royal College of Surgeons, Viscount Astor, Major General Sir Richard H. Charles, Sergeant Surgeon to the King; Brig. Gen. John H. Finney, Lieut. Col. Sir James Fowler of the Colonial Office and Director General of the British Naval Medical Department; Dr. Charles Mayo and other eminent physicians and surgeons. Among those who attended the service at the cathedral were Lieut. Gen. Sir Thomas H. Goodwin, Honorary Surgeon to King George, who represented the King; representatives of Dowager Queen Alexandra; John W. Davis, the American Ambassador, and Mrs. Davis; Sir Christopher Addison, British Minister of Health, representing the Government; delegates from the Army Council; Viscount and Lady Brice; Colonel de Page, representing Belgium, and representatives of Panama, Cuba, Peru, Canada, Argentina, South Africa, New Zealand, Australia, and Serbia.

Medical Society Elections.—The MAINE MEDICAL ASSOCIATION, at its sixty-ninth annual session held in Augusta the latter part of June elected the following officers for the ensuing year: *President,* Dr. Theodore E. Hardy, Waterville; *First Vice-President,* Dr. G. R. Campbell, Augusta, *Second Vice-President,* Dr. James McFaden, Milo; *Secretary-Treasurer,* Dr. B. L. Bryant, Bangor.

THE MONTGOMERY COUNTY (Ohio) MEDICAL SOCIETY, at a recent meeting held at Dayton, elected the following officers: *President,* Dr. A. E. Shepherd; *First Vice-President,* Dr. A. B. Brower; *Second Vice-President,* Dr. E. E. Shepherd; *Third Vice-President,* Dr. W. B. Bryant; *Secretary,* Dr. Robert C. Austin; *Treasurer,* Dr. F. D. Crowl.

Obituary Notes.—Dr. J. D. SOURWINE was found dead in bed at his home at Brazil, Ind., June 26. He was sixty-eight years of age, and was graduated from the Central College of Physicians and Surgeons, Ind., in 1896, specializing in gynecology. He was a member of the American Medical Association. Dr. Sourwine was one of the promoters of an electric line connecting Brazil and Harmony, said to be the first interurban line built in the United States.

Dr. JOHN H. CURTIS, formerly of Chicago, died in New Britain, Conn., June 26. He had been superintendent of the New Britain department of health since February. Dr. Curtis. who was fifty-six years of age, was graduated from New York University Medical College in 1886.

Dr. F. S. WARREN of Biddeford, Me., died suddenly of apoplexy June 28, at the age of sixty-nine. He was graduated from the Medical School of Maine, at Portland, in 1872.

Dr. FINLEY ELLINGWOOD of Chicago, died at Pasadena, Calif., June 29, at the age of sixty-nine. He was graduated from Bennett Medical College, Chicago, in 1878, and was active in Eclectic medical circles.

Dr. E. C. OGLESBEE of Cedarville, Ohio, died at Mt. Carmel, June 30, following an operation. He was sixty-two years of age, and was graduated from Hahnemann Medical College and Hospital, Chicago, in 1885.

COLONEL WILLIAM WINBORNE GRAY, M. C., U. S. Army, retired, died July 3, at his home in Forest Hills, Long Island. He was born in Tennessee in 1850, was graduated from Bellevue Medical College in 1875, and entered the army as assistant surgeon in 1878. He was buried at Arlington National Cemetery, Washington, D. C.

Dr. FANNY DONOVAN CONKLIN of Stapleton, Staten Island, died July 4, at the age of seventy-five. She was graduated from the Woman's Medical College of the New York Infirmary for women and children in 1876.

Dr. FRANK B. BROWN of Boston and Dorchester, Mass., died suddenly July 4, at the age of fifty-seven. He was graduated from Bowdoin Medical College in 1887.

Dr. WILLIAM AUSTIN TOMES of Brooklyn, N. Y., died June 28, at the age of fifty-five. He was graduated from the College of Physicians and Surgeons, New York City, in 1891. He was a member of the Lenox Hill Hospital Association, having served as interne in 1891-1892.

Dr. WALTER HENRY HOLDRIDGE of New York City died July 3 at the age of thirty-nine. He was graduated from the College of Physicians and Surgeons in 1903, and was a member of the American Medical Association and local organizations.

Correspondence.

THE BUREAU OF INTERNAL REVENUE AND THE PRACTICE OF MEDICINE.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—It would be instructive to learn under what section or clause of the Harrison Anti-Narcotic Act the Bureau of Internal Revenue, which is charged with the administration of this act, is empowered to lend or to withhold its endorsement of public clinics for the treatment or cure of drug addicts. This question is prompted by the generally published statement of Prohibition Commissioner John F. Kramer, who gives as his reason for this action that, "The net result of such public clinics appear to have demonstrated conclusively that the cure of drug addiction through such means is a failure and that hereafter no similar institution should have the endorsement of this bureau."

As far as any recorded evidence on the subject is available the cure of drug addiction by institutional treatment is equally a failure, although this method has been urged upon the Federal Government to the exclusion of all other in the findings of the Special Narcotic Drug Committee of the American Medical Association. In this State the same recommendation was embodied in the Cotillo Drug Bill. This was rejected by the Legislature on the ground that it made institutional treatment compulsory, to the sole advantage of these institutions. The first step toward the establishment of a drug clinic was made under the law compelling the Department of Health of this city to supply in an emergency a sufficient quantity of the drug of his addiction to an addict. This law was drawn after the evidence given before the Legislature of the unspeakable degradation under which the drug needed was obtained by an addict in vile resorts in the city during one of the periods when physicians refused to prescribe for addicts on account of the danger of so doing. This law was never observed by the Department of Health. Where application was made in keeping with its provisions the drug was refused unless the applicant consented to a commitment to a city institution.

The Drug Clinic became a necessity wherever Federal or State laws were suddenly and strictly enforced, with the result of shutting off the supply of drugs to those who, it is no exaggeration to say, could not live without them.

This was shown under the rulings laid down by the Commissioner of Internal Revenue when the Harrison Law was first enforced rigorously throughout the country. Under these rulings the prescribing of opium by the physician was surrounded by so many dangers that many refused to prescribe it not only in cases of addiction but for any purpose whatever. Under these conditions the mortality from withdrawal conditions and from suicide became so great that physicians were requested, and even urged, by revenue officials to take care of these cases until these rulings were reversed, as they were in time. The decision since made by the U. S. Supreme Court that morphine could be prescribed in the case of an addict only for immediate use and in no sense to make the addict comfortable, led to another period of disaster among the victims of this condition. This was ended, according to the accounts in the newspapers by the pleadings directly addressed to the Government of innumerable sufferers from chronic and incurable disease as well as of the aged and incurable victims of drug addiction itself.

The report of the Narcotic Dispensary of the Louisiana State Board of Health cannot have been seen by Prohibition Commissioner Kramer

before making his pronouncement on the failure of the drug clinic as a means of cure for the drug habit. This clinic is acknowledged to have been the most successful and best conducted of any of those established throughout the country. Among its objects, as given in this report, are the following: "To relieve suffering until such time as scientific treatment can be had. The basis of operation is legitimate. Supply versus illegitimate trafficking. To prevent victims from being victimized by profiteering ghouls. No 'registration' to compromise addicts or to subject them to possible blackmail. This dispensary does not attempt to cure addicts." This report was issued April 15, 1920, by the Louisiana State Board of Healtth, Merrick W. Swords, M.D., Director of Narcotic Clinic.

Clinic.

JOHN P. DAVIN, M.D.

NEW YORK.

BENJAMIN RUSH FOR THE HALL OF FAME.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—You were good enough to publish my letter in reference to the election of the names of Morton, McDowell, and Sims to the Hall of Fame in your esteemed issue of June 26. In my letter I stated that the election would take place July 1. I have since learned that the electors have until October 1 to make their decision, which gives all those who are interested time and opportunity to send their endorsement of all or of any one of the candidates mentioned to the electors or to the Senate of the New York University.

Since the publication of my last letter I have received a number of requests to include in the list of America's immortals the great Benjamin Rush, whom Roswell Park in his History of Medicine calls "the most conspicuous medical character of the century." American internists will always hold Rush in grateful admiration as an acute observer of disease. His descriptions of clinical phenomena are to-day as classic and authentic as when published, and of course I am glad to include the founder of Rush Medical College among those of our profession who should have a place in the Hall of Fame.

S. ADOLPHUS KNOPF, M.D.

OUR LONDON LETTER

(From Our Own Correspondent.)

LONDON, June 18, 1920.

The Rockefeller Foundation's Offer to University College Hospital Medical School.—It has just been announced that the Rockefeller Foundation has offered the sum of £1,205,000 (over $6,000,000) to University College Medical School and to University College, London, in the interests of medical teaching and research. At a meeting of the staff and students held in University College on June 11, the Provost, Sir Gregory Foster, gave full details of this offer. Sir Gregory, quoting from a report which is to be presented to the United States Senate, stated that he had visited New York with the Professor of Anatomy, Dr. Elliot Smith, and Drs. Blacker and Elliott, representing the Medical School, at the invitation of the Rockefeller Foundation. This Foundation had been established by Mr. John D. Rockefeller "to promote the well being of mankind throughout the world." It had made the promotion of medical education and research its special field. In pursuance of this last policy the Foundation shortly after the end of the war, conceived the idea of assisting the development of medical education and research in London. They had before them the report of Mr. Abraham Flexner, Director of the Rockefeller Home Education, New York, on "Medical Education in Europe" issued in 1912, and Sir George Newman's "Some Notes on Medical Education in England" issued in 1918. In both of these works the development of medical teaching by the foundation of clinical units was advocated in hospitals and medical schools. The knowledge gained from these two publications was supplemented by a report by Dr. Wickliffe Rose, a member of the Rockefeller Foundation, and Dr. Pearce, medical expert advisor to the Foundation, who visited London in the latter part of last year and made themselves thoroughly acquainted with the conditions prevailing in London and with the several centers of medical education. Their report was received by the Rockefeller Foundation Board of Trustees at the end of February. The Board of Trustees was greatly interested and directed its executive committee to consider in detail the University College Hospital Medical School projects and the plans for tthe improvement of anatomy which, incidentally involved an extension of physiology at the college. The scheme as a whole was summarized by the Rockefeller Executive Committee as follows: (1) An institute of anatomy, (2) increase of clinical facilities, (3) clinical laboratories planned, (4) increased maintenance costs, (5) closely unified administration. In New York the University College Hospital delegation met the members of the executive committee of the Foundation, both informally and in conference. They expressed the view that to help the scheme of development would be in full accord with the high purpose of their founder, and they would deem it a privilege to aid them. They disclaimed any idea of desiring to dictate methods or lay down conditions. Their desire was to help to carry out the schemes of development, and they therefore assumed that any funds they might offer would not be used to relieve existing expenditure, but to supplement it for the greater good of medical education and research. The executive committee were able to state that the Rockefeller Foundation offered to give to University College Hospital Medical School the sum of £400,000 "towards a building and equipment programme, substantially as submitted by the authorities of the school, and the further sum of £435,000 toward the support of clinical facilities and teaching in substantial conformity at the outset with the proposed plan," making a total of £835,000 for the Medical School. To "the University of London in behalf of University College the sum of £190,000 toward a building and equipment programme, substantially as submitted by the authorities of the College, and the further sum of £180,000 toward the endowment of laboratory teaching in substantial conformity at the outset with the proposed plan, "making a grand

total of £1,205,000, or nearly six million dollars.

Sir Gregory Foster said that it would be difficult to convey the delightful way with which the Rockefeller Trustees approached the matter, initiated it, and carried it out. In conclusion the speaker said that he believed that the gift was the greatest single gift that had ever been made for educational purposes in Great Britain. Professor Elliot Smith moved a resolution, expressing on behalf of the staff and students of the University of London, University College, appreciation of the munificent and spontaneous gift. The resolution added that, by endowing the work of the Department, the Rockefeller Foundation would ensure that the requisite facilities for anatomical teaching and research, in close conjunction with those in physiology and pharmacology, would be provided in accordance with the scientific requirements of the time. He pointed out that the general scheme of anatomical teaching in Great Britain was in a curious position. There was, for instance, no equipment for allowing students to study, in the anatomy department, such parts of the body as could be seen only by the artificial aid of a lens or lenses. There were no facilities for showing sections of embryos, or for allowing students to study this essential part of their work. Nor were there any facilities for the study of the experimental factors which determined the form of the body. It was now hoped to bring back to anatomy the parts of the subject such as histology and embryology which had been taken away from it. It had been the settled policy of University College to restore anatomy to the position which it should occupy, not only in the medical curriculum, but also in the field of medical research. Professor J. P. Hill, Vice-Dean of the Faculty of Medical Science, in seconding, expressed regret at the unavoidable absence through illness of the Dean, Professor Starling.

The American Hospital in London.—The plans for the American Hospital in London to which reference has been made on several occasions in previous letters, are far advanced. Mr. Taft is president of the hospital in America and Lord Reading in Great Britain. Lord Bryce is the British vice-president. The establishment of an American hospital in London is another bond to unite British and American medicine. It may be mentioned that during next month a great dinner organized in connection with the hospital is to be given to Dr. Charles Mayo of Rochester, Minn. This dinner will be attended by all the leaders of American medicine, and it is understood that Mr. Balfour will be one of the speakers.

Gift to the University of Cambridge.—Sir William Dunn died some two or three years ago, leaving an estate of more than £2,000,000 ($10,000,000) appointing the directors of the Commercial Union Assurance Co. as trustees for its disposal. The trustees have just allocated the sum of £165,000 ($825,000) to be expended in the building and maintenance of a department of biochemistry on a site provided by the University and for the endowment of a chair and a readership.

Statistics of Maternity Institutions and of Children's Homes and Hospitals.—It is now fully realized that in order to rear a healthy race, midwifery in Great Britain must be placed upon a proper basis and that young children must be thoroughly well cared for. An amazing amount of ignorance prevails among almost all classes as to the dangers of parturition and with regard to the feeding and care of young children, which state of ignorance can be successfully combated only by the educative measures carried out in a practical manner. The Ministry of Health is making the first move in this direction by demanding certain information from all institutions receiving resident children under five years of age. The details required include the number of cases admitted, average duration of stay, reasons for admission, condition on discharge, number of cases of infectious disease and number of deaths, with date and cause. Immediate information of all deaths from epidemic diarrhea is to be given. With respect to maternity homes and hospitals the information is to include the number of cases admitted, the average duration of stay, the number of cases delivered by midwives and by medical men respectively. The cases for which medical assistance was sought by the midwife are to be classified according to the reasons for appealing for assistance and the period at which this was required. The number of cases of puerperal sepsis, of a rise of temperature above 100.4° F. for twenty-four hours with rise of pulse rate, ophthalmia neonatorum, of "inflammation of the eyes, however slight," of artificial feeding, and of maternal and fetal deaths, have all to be recorded, with details of causes, results of treatment, and in fatal cases of post mortem findings. The Minister of Health also requires immediate and detailed information of every case of maternal mortality occurring in the institution, or due to illness contracted in the institution, and every case of notified puerperal fever.

The Health of the Nation.—Miss Olga Nethersole, the well known actress and the founder and organizer of the People's League of Health, and Dr. Eric Pritchard, the pioneer in Great Britain of an organized system for rearing young children in a rational manner, have just returned from Brussels, where as delegates of the League, they have been attending the conference of the Royal Institute of Hygiene. The impression gained by the British delegates was that, on the whole health conditions are better in Belgium than in Great Britain. One reason given for the superior conditions in Belgium is that the Belgian people are more abstemious and the incidence of venereal disease is lower by far. Moreover, the housing question is not such a serious factor in their infant mortality or general death rate as in Great Britain because there are fewer slums in the larger towns, and also because a large proportion of the population is engaged in agriculture and other outdoor occupations.

Purulent Conjunctivitis in Great Britain.—At the annual Congress of the Ophthalmological Society of the United Kingdom, held recently in London, one of the subjects discussed was that of purulent conjunctivitis. According to Dr. Macrony, an inspector of midwives in London, the incidence rate of the condition per thousand births in London varied between 10.37 in 1919 and 7.25

in 1915. In the practice of midwives the incidence per thousand was 6.5 in 1916, 6.5 in 1917, 10.75 in 1918, 11 in 1919. The later increase might be due to the greater care in notification. In 1914, out of 557 cases of inflammation of the eyes in the practice of midwives, six showed damage to the cornea; in 1919 out of 840 births in midwives' practice, fifteen had corneal damage. Mr. Sydney Stephenson pointed out that the infection was easily prevented. Credè's method of prophylaxis was the greatest step. In a series of 24,724 births up to 1895, in which Credè's method was carried out the disease occurred in only 0.655 per cent. Not every case of the disease, however, was due to the gonococcus. He reminded the meeting of the simple cleansing of the eyelids at birth practised by Samuel Haig of Camberwell, in 1879, with the result that he never had a case of purulent conjunctivitis in his practice.

Mr. J. B. Lawford criticized the recent omission from the regulations of the Central Midwives Board of all reference to Credè's method or to any substitute for it. Therefore, whether anything in that way should be applied was left to the discretion of the midwife, a very undesirable state of affairs. Mr. E. Treacher Collins proposed the following resolution: "The Ophthalmological Society of the United Kingdom wishes to urge on the Metropolitan Asylums Board, now that so large a number of cases of purulent conjunctivitis are aggregated in one institution, the Metropolitan Asylums Board Special Hospital for purulent conjunctivitis in infancy, that facilities should be afforded at it for the teaching of medical students, midwives and district nurses as to the natural history and treatment of the disease."

1. The Shattuck Lecture—Epidemiology and Etiology of Influenza. Allan J. McLaughlin.
2. Pneumonia in a Woman With an Habitual High Blood Pressure. M. J. Konikow.

1. Epidemiology and Etiology of Influenza.—Allan J. McLaughlin, Assistant Surgeon-General U. S. Public Health Service, reviews the subject of influenza at length, giving various tables and charts showing incidence, mortality, etc. From this study he concludes that influenza is a disease of great antiquity and that the cause of the world-wide pandemics and interpandemic outbreaks is the same. With a strong predilection for the winter months, influenza occurs every year. In retrospect one can detect in the mortality statistics outbreaks reaching epidemic proportions in 22 out of the 30 years since 1889. In 1918-19 the attack varied from 15 to 40 per cent. and seemed to be highest in the age group five to nine—declining in each successive age group except 25 to 34, which exceeded the rate for the group 15 to 24. The incidence in 1918-19 was greater in females than males and the disparity was most noticeable in the ages from 25 to 40, indicating, according to Frost, that the females from 15 to 45 were either more susceptible or more intimately exposed to infection than males of corresponding age. Case fatality in the 1918-19 epidemic was about 2 per cent. and was slightly higher in females under 15 and very much higher in females over 60 than in males of corresponding ages. From 15 to 60 the case fatality was much higher in males. There was great variation in 40 large cities in explosiveness of the epidemic and in the severity as measured by the excess death rates for the entire epidemic period. There seemed to be some correlation between explosiveness and the severity as measured by excess death rates—the greatest mortality being usually, but not always, in cities with a high explosive index. There was little consistency in the explosiveness of the two epidemics, 1918-19 and 1920, upon comparing the indices in the various cities. There seemed to be some correlation between explosiveness and the general death rate and the rates for the four principal causes of death—pneumonia, tuberculosis, heart disease, and nephritis. There seemed to be considerable correlation between the total excess death rates for the epidemic periods and the general death rate and the death rates for pneumonia, tuberculosis, heart disease, and nephritis. All evidence points to an immunity of a relatively short duration—probably of months rather than years. The etiologic cause is unknown. There is not sufficient evidence to warrant the view that *B. influenzæ* is anything more than a secondary invader. The claims for a filterable virus are strong, but much additional work will be necessary to make certain many things which are now only possibilities.

9. Choledochitis, Cholecystitis and Cholelithiasis. B. B. Vincent Lyon.

1. The Diagnosis and Treatment of Gall-bladder Affections.—Max Einhorn considers diseases of the gall bladder as coming within the three categories of: (1) Acute cholecystitis, without and with jaundice; (2) chronic or recurrent cholecystitis, without and with stones; (3) empyema of the gall bladder, usually with ulcerations; (4) malignant diseases of the gall bladder. The diagnosis is based on the symptoms in conjunction with the objective findings. It is important to recognize in a general way the organ affected and then, if possible, to make a more detailed statement with regard to the special disease present. The diagnosis is comparatively easy when the affections of the gall bladder run a typical course, but extremely difficult when they appear, as they frequently do, in disguised forms. It is principally in these latter conditions that one must utilize all the more refined methods in order to come to a correct conclusion. In addition to a consideration of the subjective symptoms and a physical examination the writer makes use of the *x*-ray apparatus, and employs the duodenal tube and the duodenal bucket and string. The direct examination of the bile, obtained from the duodenum, in the fasting condition of the patient, is of great importance. The more detailed diagnosis will always have to be made by a combination of all the findings, subjective and objective. Thus, turbid bile, fever, extensive leucocytosis, high polynuclear count, considerable tenderness in the right hypochondrium, in conjunction with muscular rigidity on the right side, will point toward empyema or ulceration of the gall bladder nearing perforation. Severe colicky pains in the right hypochondrium, with or without a slight rise of temperature, followed a few hours later by perfect remissions and freedom from pain, will speak for a biliary calculus. Turbid bile will substantiate the diagnosis. The same symptom complex, with jaundice and absence of bile in the duodenum, will indicate a stone in the choledochus or common duct. Intractable jaundice, cachexia, frequent distress, but no sharp colicky pains, preceding the icterus, no bile in the duodenum or presence at times of clear bile, indicate a malignant disease involving the choledochus, or the hepatic ducts. The treatment of gall-bladder diseases is divided into that of the acute conditions and that covering chronic states. In both groups medical as well as surgical therapy have their special fields. Acute cholecystitis of great toxicity, giv-

ing rise to empyema, ulceration or a perforation of the gall bladder, requires immediate surgical intervention. The indications for surgical treatment in chronic cholecystitis, with or without stones, are given as follows: (1) Comparatively severe recurrent attacks of cholecystitis, whether accompanied by fevor or not, require surgical aid. (2) Mild attacks of recurrent cholecystitis accompanied by a moderate leucocytosis (especially with an increase of the polynuclear cells) likewise require operation. (3) Chronic jaundice due to obstruction is best handled by operative measures. (4) Gall-bladder affections in which there is sufficient reason to suspect a malignant disease should be operated upon as soon as possible. Contraindications to operative procedure are found in severe heart or kidney lesions, diabetes mellitus, general debility and old age.

8. A Study of Malnutrition in School Children.—Maud A. Brown reports a piece of experimental health work carried on in the grade schools of Kansas City, Mo., in the spring of 1919. Following the influenza vacation, the children of fifty-five grade schools were weighed and measured by the classroom-weight-chart method of the Child Health Organization. The percentage of underweight, when computed, indicated that the general estimates as to the prevalence of malnutrition among school children in the country over were applicable, without exaggeration, to the children of Kansas City. The school was selected that showed the highest percentage of children who were more than 10 per cent. under weight by the standard table of Dr. Wood, with the idea of seeing what would be the effect of an intensive health service for these so-called "malnourished" children. The school selected showed 41 per cent. of its children more than 10 per cent. underweight. The physical condition of the children as revealed by examination by a physician, was recorded, and the social status of the children was ascertained by the nurse in visiting the homes. "Protective feeding," the necessary dental work, removal of diseased or enlarged tonsils and adenoids, and instruction in "health habits" formed important parts of the regime to which the children were subjected, and which the writer details and charts. The children were divided into two groups, 112 being those who signified their desire to undergo the experiment by returning the permits for school feeding, cards for which had been sent their parents, and 109, identical in respect to physical condition as nearly as could be determined, who were considered a "control group." Fourteen of the children failed to make normal gains for the period. Definite reasons for the failure to gain were found in all but one, a boy, who became thinner and stronger the more he ate, and who, being in tip-top health, was pronounced one of the "naturally thin" children. A careful study of the results forces the conclusion that the two factors chiefly responsible for the interesting showing are the work of the nurse in securing home cooperation, and the selection of food with reference to supplying the dietary deficiencies of the home on the "protective feeding" plan. One of the most interesting observations was that the children cheerfully stored away from 1,000 to 1,800 calories in addition to their customary three meals. The mothers reported that they were eating more at home also. This suggested the probability that the amount of feed needed by growing children has been underestimated. No correlation has been found between the rate of growth of these children and any of the social conditions. The time was too short to show the favorable results of the other elements of the health service. Doubtless, a few weeks longer would show a decided advantage in favor of those pupils who had defects of teeth and tonsils corrected and adenoids removed. The writer points out two facts of paramount significance: (1) These children, in spite of adverse conditions and handicaps unremoved, were so desperately in need of food that they made a gain of 278 per cent. (normal gain, 100 per cent.) or 302 per cent. gain over the control group; (2) this school, which ranked lowest (fifty-fifth) in the spring, ranked third in September, the difference, beyond reasonable doubt, brought about by nine and one-half weeks of intensive health service.

9. Therapeutic Agents in Chronic Nervous Diseases.—W. A. Jones, in summarizing this subject, holds to the view that for the majority of patients who consult the neurologist and psychiatrist isolation from their former surroundings, confinement in a well-ordered hospital, and the prohibition of visitors should be rigidly adhered to. Nervous and mental patients do better when they have been regulated by correction of their physical disabilities and forced to follow a definite mental disciplinary line of treatment. This includes all that may be said of enforced rest, not for weeks, necessarily, but perhaps for months. The establishment of order by discipline applies equally well to the physical as to the mental attitude of the patient, and this can be done successfully only by one who is trained for this work. Baths of simple type—warm tub, cool spray or Scottish douche—are of more value than many drugs. Exercise of the graduated type during the convalescent period is of tremendous value, provided it is carried over many days and weeks with but moderate increase in the time given to such exercise. Sufficient examination should be made from time to time to assure the physician, as well as the patient, that nothing important is overlooked. The ordinary routine visits must be suspended at intervals to make this impression lasting. One person should be responsible for the patient, and only minor details should be left to subordinates. The patient should be left alone, and without a special nurse, as soon as possible; otherwise he becomes dependent on the nurse not only for his physical but for his mental habits. Massage is not absolutely essential either to the patient's comfort or to his improvement. The coddling of patients should be eliminated. Occupation, unless it is carried on by a trained and skilled worker, is of very little value, and means only the use of time which might be employed in a more profitable manner. Many patients require a firm, guiding hand. Others require the influence of a strong and dominating will, together with mechanical or drug restraint, and confinement in a suitable room. The writer holds that if this method of treatment is begun early in selected cases, the recovery is much more rapid and satisfactory.

2. Researches on the Treatment of Benign Tertian Fever.—Hugh W. Acton records studies made by his associates and himself in the Malarial Research Laboratory, British Malarial Depot, Dagshai, Simla Hills, India. Hitherto the treatment of malaria was summed up in one word, "quinine," and the only points at dispute were the methods of administration and the length of time this alkaloid should be taken. The other alkaloids of cinchona bark have been used by numerous observers, but as far as the writer is aware have never been accurately tested. The universal belief that quinine is equally a specific for all types of malarial fever will have to be abandoned before any material advance can be made in the treatment of these fevers. Malarial fever, in Acton's opinion, should be regarded not as one disease, but as a group of three different fevers, due, as is already known, to three distinct parasites, and two at least of these require different alkaloids of cinchona bark for their treatment. Many of the previous workers on the action of the cinchona alkaloids were compelled to work under unfavorable conditions. The writer and his associates were fortunate in treating British troops under their immediate command, where every detail could be followed in the treatment. Every one of the recorded cases remained for two months or longer under observation after completion of treatment. The conditions required to test a particular cure for malarial fevers are summed up briefly as: (1) The population under investigation should be sufficiently large and homogeneous. At least 100 men should be treated, and the parasites must be of the same species and found microscopically in every case. (2) Reinfections must be excluded during treatment and observation. (3) Eight weeks should be the minimum period of observation required after treatment. An additional 6 per cent. of the relapses observed in this period gives the correction for what could happen if the cases were observed longer. (4) The experiment should be repeated if necessary to eliminate the errors due to chance distribution. The notable absence of the malignant tertian parasite among the cases studied was explained as due to the specific action of quinine, for all the cases had undergone a course of treatment with this alkaloid before arrival at the depot. Out of 992 parasitic findings, only 14 individuals were found to harbor the malignant tertian parasite. There were 978 showing benign tertian infection. The specific action of quinine on the malignant tertian parasite explains how this parasite disappears from the blood of malarial patients who have returned home from the tropics, as such individuals have been well drugged with quinine. The second important point that became apparent upon analysis of their results was the low cure-rate of quinine in benign tertian infections. Out of 663 cases of this infection treated with quinine there were 32.4 per cent. of cures; nearly 70 per cent. of the cases relapsed in spite of treatment. After noting this low cure-rate of quinine in benign tertian infections it was considered that by giving short courses of treatment a larger number of effective men could be obtained in a shorter space of time than by giving the long courses of four months quinine treatment. The group selected for this study consisted of 475 men who had been treated by quinine for malaria and sent up to Dagshai, where they were placed on an iron tonic. Out of these, 277 relapsed, and benign tertian parasites were found in every one of these relapses. Out of these 277, 204 could be observed for the full two months after a further course of treatment, and of these 145 relapsed. Ninety-five could be followed for the full period after a second course of treatment at Dagshai, and 76 relapsed; 45 of these could be followed after the third course, and 32 relapsed. Ten of the 32 relapses could be followed after the fourth course, and 8 relapsed. The actual cure-rate for these four courses at Dagshai work out at 28.9 per cent., 20 per cent., 28.28 per cent., and 20 per cent., respectively, or an average of 24.4 per cent. for each course of treatment. The maintenance of the cure-rate about a constant of 25 per cent. from the first to the fourth course of treatment is a very important fact, as it indicates that neither does the parasite become more and more quinine resistant, nor does the host's resistance alter; otherwise the cure-percentage should diminish with each subsequent course. Clinically one cannot say whether a given case will be cured with one or many courses; it seems immaterial whether the patient is undergoing his first or fourth course, for with each course he stands an equal chance of cure. Discussing the rate of parasitic destruction, the writer calls attention to the fact that the asexual malignant tertian parasite forms 8 to 12 merozoites every 48 hours and is most influenced by quinine. The asexual benign tertian parasite forms 16 to 24 merozoites every 48 hours and is less easily destroyed by quinine. On the other hand, the quartan parasite has the lowest rate of multiplication, 8 to 12 merozoites every 72 hours, and is the most refractory to quinine. This difference in the multiplication rate is not sufficient to explain the difference in cure-rates by quinine, although it undoubtedly plays a part. Cinchona febrifuge (a preparation containing the total alkaloids extracted from cinchona bark, made at the Government factories in India and issued in the form of 3½ grain tablets) was found to be better than quinine in benign tertian infections. Fourteen alkaloids have been isolated from the various species of cinchona bark. These are described, and the factors on which their parasiticidal action depends discussed. The levorotary alkaloids, quinine and hydroquinine, have a specific action on the malignant tertian parasite, while the dextrorotary alkaloid quinidine (hydroquinidine has not been tested as yet) is more powerful than quinine in its action on the benign tertian parasite. The corresponding levorotary isomeride cinchoindine behaves very similarly in its action on the benign tertian parasite. Both these isomerides are much less toxic to man than quinine. It is therefore concluded, from the chemical study of these alkaloids, that: (1) The methoxycinchonines—viz., the quinine series—are less toxic than the cinchonine series; (2) the hydroalkaloids are more stable; (3) the levorotary alkaloid quinine is a specific for the malignant tertian parasite, while the dextrorotary alkaloid quinidine is the best alkaloid tested so far for the benign tertian parasite. The exact action of these alkaloids on the malarial parasite cannot be determined without much more chemical and experimental work than has been given to the subject.

Venous States of the Menopause.—Poulain quotes Vinay's definition of the menopause as the interval between perfect regularity of the menses and their total suppression. This is in a way defective, for the definite and permanent suppression of the discharge is not coterminous with the suppression of the clinical phenomena of the menopause. In the artificial menopause the woman's troubles only begin with the complete suppression of menstruation. The behavior of the woman's organs after the suppression of this function varies with her constitution and inheritance. If of a nervous or hysterical makeup, she is apt to be more nervous, and some one of the neuroses may spring into existence for the first time. This holds good for other predispositions, such as the tendency to cardiovascular troubles, varicose veins and the like. A study of the woman's past menstruation is often illuminating as in the case of a young girl who, when her courses stopped for any reason, developed varices of the legs. The anatomical connection between the circulations of the uterus and lower extremities is of course well known. Fiessinger has published a monograph on the subject of the cardiopathies of the menopause, these being either reflex in nature, or due to hysteria and neurasthenia. The connection between these phenomena and the venous states discussed by the author is rather fugacious. On the other hand, there is an intimate connection between venous states and the hot flushes and analogous vasomotor behavior of women at the climacteric. The stasis in the venous circulation of the limbs is closely related to the stasis in the uterus and pelvis, from Nature's attempt to initiate a menstrual molimen after the function is abolished. The symptomatology of the venous stasis of the legs and pelvis is a rich one, including cramps in the calves, cold feet, various dermatoses, edema, and of course all of the phenomena associated with varices themselves. The gouty subject appears to suffer especially in these cases.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON MEDICINE.

Stated Meeting, Held January 20, 1920.

DR. CARY EGGLESTON IN THE CHAIR.

A Discussion of Rare Cases of Anatomical Diagnosis.—Dr. NELLIS B. FOSTER presented these cases which, he said, bore no relation to one another, but served to illustrate some of rare conditions that one met from time to time.

CASE 1.—This patient came into the hospital giving a history of attacks said to be indigestion which had been recurring from time to time for a number of years. None of these attacks had been serious; one of the recent ones had been diagnosed as mild or chronic appendicitis. That was all the history that they were able to secure. Just before admission to the hospital the abdominal pain had become worse and vomiting had begun. This continued until the end and was associated with all the symptoms of intestinal obstruction. In this case the diagnosis could have been made out, and, in fact, one of the staff suggested the correct diagnosis, but means were not used to establish it. The second day after admission the man died in collapse. The autopsy revealed a diaphragmatic hernia and all the intestines in the thoracic cavity. In commenting on this case, Dr. Foster said that diaphragmatic hernia was not as rare as it was supposed to be, but its diagnosis was not often made prior to operation for obstruction, the acute attacks being often diagnosed as appendicitis. It culminated with a severe attack that might or might not be due to intestinal obstruction. The typical signs of pneumothorax might be present. The diagnosis could be established only by the *x*-ray and the bismuth meal, when it would be found that some portion of the intestinal canal was in the thoracic cavity. Dr. Janeway, years ago, showed a case with this condition.

CASE II.—This patient, Dr. Foster said, was supposed to have a very common condition until the diagnosis was made post-mortem. He was a young man, 23 years of age, complaining of precordial pain, hoarseness, dyspnea ,and dysphagia. At the time of his admission to the hospital these symptoms were not severe in degree and the rapidity with which he became worse was astonishing. His whole time in the hospital was seventeen days. At first the signs did not confirm the symptoms of aneurysm of the aorta; it was not until after a week or ten days that the signs of pulsation in the chest appeared. The terminal picture was hemorrhage from which he died. It was thought that he had an aneurysm of the aorta. Instead of this, however, an exceedingly rare condition was found, namely, a dissecting type of aneurysm of the pulmonary artery, with rupture into the esophagus. This was a rare condition and he did not know how the diagnosis could have been made.

CASES III AND IV.—Dr. Foster said that he had gone through the literature rather carefully and had discussed these cases with genitourinary surgeons in New York, and he felt that they presented an unusual condition. The first man reported sick with a specific urethritis and was treated locally until he developed abdominal pain and fever; these symptoms were associated with constipation. Physical examination at the time he came into the hospital did not show anything in particular. Fever was not unusual with posterior urethritis and therefore it was supposed to be due to the urethritis. After a brief stay in the hosiptal he developed diarrhea and burning urination, and later became stuporous; the fever continued and there was ptosis of the right eyelid and dropping of the right corner of the mouth. Dr. Foster stated that he first saw the patient at this time. The right pupil was larger than the left; there was weakness of the left arm particularly, and of the left leg to some extent. There was no perceptible change in sensation. There was some weakness in the extrinsic muscles of the right eye. A few purpuric spots were observed on the body. Examination of the cerebrospinal fluid showed nothing in particular that would excite suspicion. It was thought that the man had a Neisserian infection, septicemia and cerebral emboli. He became gradually worse, lapsed into stupor, had convulsive seizures, and died at the end of forty-eight hours. At autopsy there was discovered a posterior urethritis, prostatitis, thrombosis of the periprostatic veins, and vegetative endocarditis; there were multiple abscesses through the liver and kidney. A pure culture of the streptococcus was obtained from the blood. What occurred in this case was what happened not infrequently following ill-advised or inappropriate treatment of urethritis, namely, there was an extension of the inflammation, and the continuity of all the tissues was broken, giving a portal of entry for general infection.

The fourth patient was admitted to the hospital on account of a bubo and urethritis. The bubo was incised, after which the patient had slight fever. On the third day following the incision there was a sharp rise in the temperature. The patient complained of pain in the left side, and examination revealed signs of fluid in the left chest. Aspiration showed a thin pus. Dr. Foster stated that he advised against operation at this time, but his advice was not considered sound. Operation was performed and death followed. At autopsy an abscess was found near the surface of the left lung which had ruptured into the pleural cavity, giving rise to an empyema. There was septicemia taking origin in the prostate as in the first case. The pus had also entered the pericardium. These were not uncommon pictures for the genitourinary surgeon to see following inappropriate treatment of urethritis, giving rise to posterior urethral abscess and then to a general septicemia.

CASE V.—This patient was admitted to the hospital suffering from a sense of compression in the chest and dyspnea. Two weeks previously he had received an injury which he regarded as slight. In the course of a few days the dyspnea and distress in his chest developed. Examination revealed fluid in the left chest, bulging, flatness, and the breath sounds were very distant or absent. The heart seemed to be pulled to the right. The chest fluid showed an increased cell count; there was a high leucocyte count, and a high temperature. The patient was kept under observation for four months, during which time the temperature ranged between 97° and 102° F., with periods of remission. Aspiration was done repeatedly in order to keep the patient comfortable by relieving his dyspnea. After a few aspirations it was recognized that they were not dealing with a simple effusion of tuberculous origin. The picture was suggestive of neoplasm. The necessity of these aspirations was evident from the fact that he was aspirated thirty-four times during this period and 42,000 c.c. of fluid removed. The fluid was never blood-tinged, and this was interesting, because it was usually said to be blood-tinged in the presence of neoplasm. In his personal experience blood-tinged fluid occurred as often with tuberculosis of certain types as with neoplasm. Necropsy showed a sarcoma of the pericardium extending to the pleura.

CASE VI.—This patient, a woman 42 years of age, was seen first in the eye service on account of failing vision. She gave a history, for the past two months, of bleeding gums, which was quite obstinate and difficult to control. A week before admission her sight had begun to fail in both eyes about equally; she could see light but could not count fingers. Retinal examination showed a bilateral optic neuritis. The patient's mouth was so sore that the exact state of her gums could not be determined. It was thought that she had scurvy, but that seemed to be ruled out by the fact that she was well-to-do and her diet had not been of a character to produce scurvy. Finally, in lieu of a more definite diagnosis, her condition was diagnosed as purpura. She was transferred to the medical service of the hospital and attempts were made to control the hemorrhage by means of various styptics, etc. It was not easily controlled, however, and the amount of blood lost could not be readily estimated. On one occasion it was estimated that she lost one-half a pint of blood. The hemoglobin went down to where it could not be read with any accuracy. In order to do any-

thing for the woman it was imperative to stop the hemorrhage so it was finally decided to extract her teeth. The first attempt to extract a tooth nearly resulted fatally. All the blood tests had been made and the clotting time found to be normal. Finally the hemorrhage stopped but he did not feel that the measures employed had been responsible for its control. The patient had thirteen teeth extracted. This was done by giving a blood transfusion three days in succession before each extraction. A strange thing then happened; the patient recovered her eyesight and was finally able to read. While her eyesight became practically normal retinal examination showed that there was still a degree of optic neuritis. She was finally discharged from the hospital after being there for many months. After being home for four months she came back to the hospital, complaining of shortness of breath. Examination showed fluid in the chest. Following this discovery, Dr. Foster was hastily summoned. He found the woman suffering from dyspnea. She was aspirated and a slightly blood-tinged fluid obtained. This gave her a certain amount of relief and she seemed not at all in a serious condition. Early the following morning she was *in extremis*, suffering severely from dyspnea. The fluid had re-accumulated suggesting that they were dealing with something of a neoplastic nature, using that word in a very generic sense. The patient was tapped again and the fluid obtained was almost pure blood. The red blood cells numbered approximately one million per c.c. The diagnosis at autopsy was chloroma. In this condition the symptoms were pretty definite in a general way. There were two types of chloroma, one causing exophthalmos and the other impairment of the vision even to blindness, and the only other symptoms being a certain degree of anemia. In such a case the tumors might not be visible, and in fact, in the cases he had seen, Dr. Foster said, they had not been visible. The tumors were usually found in the bones of the skull or jaw. Chloroma was somewhat allied to sarcoma. The tumors were widely scattered; if in the skull they gave rise to eye symptoms; if in the thorax to symptoms referable to the lungs.

Dr. L. T. LEWALD said, with reference to the first case, that diaphragmatic hernia, he believed, as Dr. Foster had stated, was just beginning to be recognized as much more common than had been thought to be the case. Personally, he had seen four cases, one in a very young child. He was inclined to believe the condition was a congenital one, although a number of cases had recently been reported as though they were due to traumatism, especially among men who had been in the service. He had seen no case in our own service, but some were reported in the French literature. These might have been congenital and not recognizd until they had entered the service and later had received some traumatism. In one of the cases the diaphragmatic hernia was caused by a bullet having passed through the diaphragm. But in some of the other cases it was supposed to have resulted from some traumatism caused by an explosion or pressure without the entrance of any foreign body into the body of the subject. Such cases he regarded as of congenital origin. In the case of the child there was a hernia of the stomach into the chest cavity. A diagnosis of pyloric stenosis was made, as the child had vomiting attacks and the *x*-ray showed that the child had gastric retention. It was thought that an operation was necessary and Dr. Downes, instead of attempting to deliver the stomach into the abdomen, performed a gastroenterostomy, and closed the diaphragm around this. The stomach remained in the chest cavity and emptied itself through the gastroenterostomy opening. In another case of diaphragmatic hernia, under the care of Dr. Mathews, the stomach and part of the large intestine were in the chest cavity. A repair of the diaphragm was successfully made and a year after the operation the case remained cured. One other case had come to his notice. This was in a very elderly woman, who had always suffered from attacks of indigestion and pains in the chest. *She* believed her stomach was at fault, and always felt it in her chest, while her doctors rather scouted the idea. On *x*-ray examination, however, the stomach *was* found to be entirely in the chest cavity. She declined any operative interference. With reference to Dr. Foster's last case, chloroma was a very interesting and rare condition. He had seen two cases of chloroma which gave the same symptoms that Dr. Foster's case gave, but differed in that they presented typical tumors of the scalp and skull. The *x*-ray showed these characteristic bone lesions, consisting in a peculiar infiltration beneath the periosteum, and changes in the medullary portion of the bone and a separation of the sutures of the skull. He felt that the diagnosis of chloroma could be made by careful *x*-ray examination of the bones.

Dr. E. LIBMAN said that in the past ten years he had seen several cases of chloroma without bone lesions visible during the lifetime of the patient. Help could be obtained in the diagnosis of such cases by the so-called "chloroma cells," which were first described by Butterfield and himself. It was not necessary to describe these cells; they were described in a paper by Butterfield, published in the "Folia Hematologica" in 1909. To be of any value in diagnosis, these cells must be present in abundance. Even when they were found in abundance, they were not specific for chloroma, as they were also found abundantly in an occasional case of new growth, and in the forms of leukemia which were characterized by aggressive tumor formations, and which were occasionally termed "leucosarcomatosis." If then such cells were found abundantly in a case of leukemia, one diagnosed that the patient was suffering from leucosarcomatosis, and a diagnosis of chloroma only if there were typical bone tumors or if the typical green coloration was found at the post mortem table. As regarded the diagnosis of mediastinal neoplasms, he had during the last two years been aided greatly by looking for the presence of fixation of the larynx. In all the cases of mediastinal neoplasm which he had seen during the last two years the larynx could not be moved upward. He did not know how often this might occur with aneurysms. The symptom was of course to be sharply differentiated from the tugging which was generally known as the Oliver Cardarelli symptom. One must be careful in the use of this sign, because there were people, particularly people with short necks and rigid tissus, in whom the larynx was normally quite fixed. After some experience one learned when to disregard the fixation as of no value in diagnosis.

Dr. MAURICE FISHBERG stated that he had had five cases of eventration of the diaphragm. In one case both the stomach and the splenic flexure were detected in the left chest. Many cases of eventration of the diaphragm were reported as due to traumatism. He thought, however, that they found eventration of the diaphragm quite often if they looked for it carefully. Large tuberculous lesions might pull the diaphragm to one side, and a diagnosis of this condition could be made by physical examination of the chest, and nine times out of ten without the aid of the *x*-ray, or the ingestion of bismuth. Dr. Fishberg cited a case in which the signs were those of pneumothorax, but in which after giving bismuth the bismuth was found in the upper left side of the chest. He thought if Dr. Foster had borne in mind the possibility of eventration of the diaphragm he would have made the diagnosis. Of tumors of the mediastinum 30 or 40 per cent. had a sanguineous fluid, but one must not jump at the conclusion if he got sanguineous fluid that he necessarily had a tumor of the chest. If the first puncture yielded a sanguineous fluid there was probably a tumor present, but if there was no sanguineous fluid on the first puncture and then one got it at the third or fourth puncture it was probable that the sanguineous fluid was the result of traumatism inflicted during the punctures.

Dr. FOSTER, in closing, said that what one meant by chloroma was simply a tumor with greenish color, one in which a cross section showed a greenish mass. No two pathologists agreed on each point in the morphology of these tumors; for them as clinicians the point was that chloromas and leucemic tumors might or might not be associated with blood findings characteristic of these conditions, and if there was nothing characteristic in the blood and the tumors were not found, a case might be taken for secondary anemia.

Ultimate Results in the Treatment of Chronic Nephrosis with the High Protein Diet.—Dr. ALBERT A. EPSTEIN read this paper. He said that since the publication of the paper on the "Nature and Treatment of

Chronic Parenchymatous Nephritis" in 1917 he had had the unusual opportunity of observing and treating 28 cases of the type described. As pointed out in previous publications, these cases were characterized by the usual clinical manifestations and more particularly by changes in the blood chemistry, namely, reduction in the amount of protein in the serum, percentage increase in the globulins of the serum, and varying degrees of increase (from moderate to very high) of the cholesterol content of the blood. The degree of chemical change in the blood, as just mentioned, was proportionate to the severity and the duration of the albuminuria. Certain cases which belonged in this group of nephropathies which presented no other symptoms than an intense albuminuria, revealed the chemical changes of the character described above, so that, chemical analysis of the blood showing these changes constituted the most important guide, both in the diagnosis and treatment of the condition. For the reasons stated in the previous communications, these patients were invariably put on a relatively high protein diet which was at the same time poor in carbohydrates and fats. From the experience thus far gained this mode of procedure in the treatment of the condition yielded exceptionally good results. This was confirmed by the experiences of other men who had recently put their cases on record. (Sir C. Allbutt, *Brit. Med. Jour.*, Oct. 12, 1918; D. McKay, *Indian Med. Gazette*, August, 1919; MacLean and DeWesselow, *Quarterly Jour. of Med.*, July, 1919.) The treatment must be persisted in; and the best guide as to its beneficial effect was the progressive reduction in the cholesterol content of the blood, irrespective of whether the edema was present or not. The effect of the treatment was not only efficient in reducing subcutaneous and serous effusions but eventually led to the cessation of the albuminuria and a complete recovery of the patient. As an instance of the need of perseverance, one case had been encountered in this group which required three years of the high protein diet to effect a cure. There was reason to believe that the high protein diet was indicated in most instances where a protracted albuminuria of severer proportions was present, no matter what the ultimate cause of the albuminuria might be.

Dr. FENTON B. TURCK expressed the opinion that this paper was of great importance because it opened up the subject of cell necrosis. The disease of the kidney was but a part of a general condition, just as in the eclampsia of pregnancy where one found an autolysis of the maternal tissues as the etiological factor in the kidney manifestations. In all conditions in which there was broken down or autolyzed tissue there resulted a nephrosis, and the cause was the autolysis of the tissues themselves. This had been shown in animals in which as a result of starvation autolysis of the tissues occurred and edema resulted. It was also shown that water was produced more rapidly when there was a partial starvation or deficiency feeding. Some years ago experiments were carried out by the speaker in which partial starvation was produced by the feeding of beef extractives. They had administered beef extracts and colon bacilli and as a result produced in the animals partial starvation and nephrosis with a kidney edema, and even ulcer of the stomach and duodenum. By the injection of autolyzed tissue one could produce the same condition as though the extracts of beef were administered. By removing the extractives and fats from beef there would remain 45 to 50 per cent. protein against 22 to 25 per cent. in normal meat. He had used this clinically in kidney disease for the last fifteen or twenty years and had found it one of the most effective methods of treating kidney disease. He had published in 1905 or 1906 a number of cases in which this method was used in the treatment of kidney disease, which was undoubtedly brought about by the autolysis of tissue. Recently he had been injecting autolyzed human tissue, injected into the horse, to produce a serum used in conjunction with extract-free meat in treating kidney disease, and with surprisingly good results. The meat was prepared by soaking it in cold water, and then under steam pressure removing the extractives; this hydrolyzed it and rendered it the best type of protein feeding. The antibodies produced by injecting a horse with autolyzed human tissue were very effective in producing detoxication and prevented further autolysis. Of course in these kidney conditions there might be a complicating infection but they were primarily due to autolyzed tissue.

Dr. ADOLPH I. RINGER said he could not possibly conceive that this theoretical explanation of chronic nephrosis was correct. These cases so far as the etiology was concerned invariably gave a history of infection at one time or another. In tracing the beginning of a disease one could not say definitely that it was due to a certain infection, since there were very few individuals who had not had an infection at one time or another during their lives. So while it might be very difficult to prove that the condition was due to infection most all of these patients gave a history of one or more infections. It was also known that the incidence of nephrosis was more frequent in women than in men, and especially during pregnancy when there was a certain amount of toxemia and a greater possibility of infection. In regard to the occurrence of nephrosis in animals in which there was no edema, Dr. Ringer said he had worked with rabbits that were completely nephrectomized without having had edema result, and the reason was because there was a large amount of fluid lost through expiration, and as a result the edema was not so well demonstrated in animals as in people. The reason for the edema in human beings was because they were not able to eliminate the chlorides. As to hypertension and the reason why one did not find hypertension in the cases Dr. Epstein described, might be found in this fact that the nitrogenous material was elminated well. He could conceive that the blood pressure might remain entirely normal and yet this peculiar condition might be present. As to the diet, Dr. Ringer stated that he had had five or six patients who had been treated with the high protein diet, some for a short and some for a longer period, and after the diet were in about the same condition as before. He was inclined to think it was the low chlorides in the diet that were responsible for the result. In every instance when there was an increase in the chlorides in the diet there was a certain amount of decrease in water elimination. He did not use diuretics for the reason that the chlorides in the blood possessed the best diuretic qualities, and if the kidney failed to respond to salt in the blood it would not respond to the effects of diuretics. In cases in which there was no diminution in the edema this seemed to be due to nothing except that the individual could not excrete chlorides. Cut the chlorides down and the edema would disappear.

Dr. MOSENTHAL said there were many points in Dr. Epstein's paper worthy of careful consideration and that would be of great benefit in the treatment of nephrosis. First, in regard to the interpretation of the term nephrosis. This term had come to be used during the last decade and was being accepted tacitly. From what he had heard to-night they were associating nephrosis with hypertension. Nephrosis was only a type of nephritis showing changes a little different from those of an ordinary nephritis. In acute nephritis there was a different type of nephrosis, and in pregnancy with nephrosis one might have hypertension. The theories and practice of Dr. Epstein had helped them to a better understanding of the condition and had enabled them to get better results in the treatment of nephritis. If one did not entirely agree with the theories, the practical results led one to believe that there was something to be said for them. There was no question but that a few cases of diabetes suffered with edema; the two conditions could coexist and the presence of one did not preclude the existence of the other. In the treatment of cases of nephrosis they were going to obtain something from the high protein feeding that could not be obtained in any other way. His experience was that if these patients were kept on a high protein diet the edema disappeared sooner or later, and it disappeared in one of two ways. It might disappear slowly over a long period of time, as an oliguria, or it might disappear in a short time, its disappearance being manifested as a polyuria. That fact meant something and something very definite. That something, he believed was that there must be a chemical recovery throughout the body at the time the polyuria took place which was responsible for the physical and mechanical changes, which would have to

be looked for in the capillary blood vessels since they had become permeable to materials to which they were not permeable before. In other words nephrosis was a constitutional disease. At present he believed the edema was associated with salt retention and that changes in the blood vessels were responsible for the salt retention. The condition would therefore be corrected by a salt-free and high protein diet. In the speaker's opinion there was only one way of treating the anemia that was present in these cases and that was by a high protein diet. It had been demonstrated that the high protein diet did not increase the albuminuria and did not increase the blood pressure. In a number of cases the albuminuria continued in spite of high protein diet but the patient was put in a much better physical condition.

Dr. LIBMAN said that he could not be quite sure that he agreed with Dr. Epstein's nomenclature, because the condition described by Dr. Epstein was not sharply defined. The acute cases of glomerular nephritis with edema, for instance, could not be due to this mechanism. Just how many cases were due to this mechanism, he could not say, but he thought that they were quite infrequent. Some cases of kidney disease with edema were relieved by the use of the Karrell diet, and the mechanism described by Dr. Epstein could not explain such cases. Other cases could be relieved by diuretics. Dr. Libman cited one case where no method had been of service except the use of oil of juniper. It was important that a definite pathological basis or a definite physico-chemical basis should be described for the cases which might be benefited by the method which Dr. Epstein was employing. The relationship of the ductless glands to the kidney were of great interest. It was well known that there might be albuminuria and renal changes in cases of thyroid disease. It would have been a good plan if Dr. Epstein had stopped the high protein feeding in the cases in which the thyroid therapy was added. Dr. Libman cited one case in which all the usual methods of treatment had been employed, and unusual diuretics had also been tried, but no result had been obtained until Dr. Epstein administered the high protein diet. The result was a brilliant one. It was evident that there were cases in which remarkable results could be obtained, and until one can tell definitely which cases belonged in the group that could be improved by the method, the method should be tried in all cases in which the ordinary methods did not give results. It was evident from Dr. Epstein's studies that the high protein feeding had done no harm in the cases in which good results had not been obtained.

Dr. JESSE G. M. BULLOWA said it was important to recognize another element in edema besides the salt and water, namely some emulsiostatic substance which might come from an infected focus. In some cases after the removal of the focus there was a disappearance of nephritic phenomena. The disappearance of edema occurred critically. Strange as it might sound, in the Karrell diet there was an actual concentration of salt in the tissue due to the withholding of water. The emulsion state was broken by a concentration of ions and it mattered very little whether they were salt or albumen ions. Soap makers realized this when they clotted out the soap or broke the emulsion state with salt. The emulsion phenomena applied to the cells as well as to body fluids when accomplished in the kidney and other body cells and the improvement might be thus explained. It was important for the section to remember that this method of treating nephritical edema was not new. In 1904 there was a discussion on the diet of nephritics at the International Medical Congress at which Friedrich Müller and Fernand Widal contributed. Widal there recommended in the discussion of his achloride diet the inclusion of 500 grams of beef, the amount used by Dr. Epstein.

Dr. EPSTEIN, in closing, said that he could not answer all the statements Dr. Ringer had made because it would require a complete review of the subject. Chronic parenchymatous nephritis was recognized as a clinical entity, in most instances, without a traceable origin. It seemed to him to be an error to regard this condition as a result of an infection. It seemed furthermore erroneous to regard infections as exclusively localizable in their effects, for the reason that infections might produce a generalized systemic injury which might manifest themselves in a perversion of metabolism. The frequent untoward effects of infections in diabetes might be cited as an example. The criticism of Dr. Mosenthal in regard to the term used (chronic nephrosis) was perhaps in place, but at the present time we had no term which was applicable to this condition, which must be differentiated from chronic diffuse nephritis. In the type of case presented under the heading of "chronic nephrosis" definite chemical changes are found in the blood, to which was also ascribed the retention of water in the body. These changes were not observed in any other form of renal disease, and were undoubtedly of some definite significance, whether the present interpretation of the findings be correct or not. The retention of water in the body occurs in conditions in which the kidney was not involved. Starvation edema was the best example of such conditions, and it was known that such edema subsided promptly when proper and sufficient dietetic measures are instituted. Dr. Epstein drew attention to the fact that cases of "chronic nephrosis," even in the most extreme forms, were capable of complete recovery, and it seemed to him that the high protein diet was the only logical treatment available at the present time. Experience seemed to bear out this claim. To assume as Dr. Mosenthal did, that chronic nephrosis was more or less a self-terminated condition, dependent on the vagaries of the walls of the capillary blood vessels, was not in keeping with the data which we possessed in regard to the exchange of fluids between the blood stream and the body tissues. To explain the various phenomena affecting the water exchange in the body on the basis of a changed permeability in the walls of the capillary vessels was assuming a premise for which we possessed no scientific proof. In reply to Dr. Bullowa's statement that Widal made use of large quantities of beef in connection with his achloride diet, Dr. Epstein expressed his surprise that Widal should have attributed the improvement which he observed in his cases to the low chloride content of the diet, rather than to the high protein feeding.

The Intravenous Use of Drugs in Oil.—Dr. H. R. MILLER gave a lantern slide demonstration showing the experiment they had made from which it was possible to say that: (1) Normal dogs could receive intravenously amounts of olive oil in doses of 1 to 15 c.c. at a single injection, the total amount of oil representing 60 to 80 c.c. in four to five weeks. (2) Drugs such as adrenalin or crystalline strophanthin, when given in oil intravenously, exhibited (as compared with aqueous administration of the same drugs) a gradual effect, a less intense action and a markedly increased duration of action. It would seem to be feasible to employ these drugs in oil so as to avoid the striking, exaggerated, and sometimes erratic results obtained from aqueous administration in human beings. (3) Subcutaneous inoculation of adrenalin in oil caused a very prolonged effect measured by the pupil dilatation phenomenon described by Meltzer. The subcutaneous use would seem to be indicated for bronchial asthma and urticaria. (4) It seemed to be of advantage, when using drugs in oil intravenously, to use small amounts of oil inasmuch as the effect of the drug appeared to be diminished when it was introduced with largely increased amounts of oil.

Dr. BULLOWA stated that he had had the opportunity to confirm the observations of Dr. Miller though with another drug. A case of diabetes insipidus had received for two years injections of pituitary substance once or twice daily. Various pituitary preparations had been used. A dessicated extract of pituitary substance was dissolved in olive oil and found to have a much longer effect than when given in any other form. He had used the aqueous pituitary extract as an emulsion with oil and found the effect lasted no longer than when it was used without oil.

Dr. MILLER, in closing, pointed out that aside from all theoretical speculation it was absolutely safe to use olive oil as a therapeutic measure. It would be possible to carry out studies along metabolic lines by flooding the system with oil. Clinically it might be of value to use oil as a vehicle for certain drugs to avoid an abrupt and overwhelming effect in patients suffering from damaged cardiac condition and in acute disease. Possibly it might also be useful in bronchial asthma.

SECTION ON SURGERY.

Stated Meeting, Held February 6, 1920.

DR. SEWARD ERDMANN, IN THE CHAIR.

Compound Fracture of the Femur.—Dr. JAMES N. WORCESTER presented this patient, a policeman 29 years of age, admitted to the hospital April 26, 1919, and discharged June 20. Just before admission he attempted to jump on a moving automobile, slipped under the machine, and the wheel ran over his left leg. The fracture sustained was compounded on the outer side and the leg was bleeding profusely. The joint was full of blood, and the skin badly lacerated over the anterior and under sides of the knee. There was 2¼ inches shortening. The wound was thoroughly cleansed with soap, water, and ether. It was iodinized and a Thomas splint with glue traction applied. No improvement followed this procedure, so on May 2 a Steinmann pin was inserted in the tibia, with the patient under anesthesia, and an attempt made to reduce the fracture with heavy traction. The patient improved somewhat. Forty-five pounds traction for twenty-four hours was then applied under anesthesia but no further improvement. The point of compounding was badly infected superficially and the whole skin area about the knee very dirty. The Steinmann pin was removed on the twenty-second day on account of infection. Eight days later incision was made at the points of entry and exit and following this the infection rapidly subsided. By the time the skin was in proper condition for any operative interference the fracture was consolidated. From the time of the insertion of the pin active and passive motion of the knee joint instituted and, as the patient was very anxious to help, this was really done. At present the function of the knee was entirely normal; the patient walked and ran. There was one and one-half inches shortening which was entirely taken up by raising the heel. The sinus from the pin had persisted until within a few weeks and was now entirely healed. The patient had solid union at eight weeks and walked at twelve weeks.

Fracture of the Femur.—Dr. E. M. ARMSTRONG presented this patient, who was admitted to the hospital on September 17, 1919, after having fallen from a roof a distance of twenty feet and striking on a spike fence. The spike had penetrated the posterior portion of the thigh at the junction of the middle and upper one-third, with a transverse skin wound, on the posterior and inner aspects of the thigh. The boy was operated on one or two hours later. There was a transverse laceration of the adductors, the biceps, and semitendinosus muscles. In the beginning it was a little difficult to know what to do to make the wound clean because of the deep laceration. A superficial debridement was done with excision of lacerated muscle and ice-tong traction applied, which rotated the lower fragment outward. The wound healed deeply, leaving the skin wide apart and with a gaping granulating area. This was skin-grafted. The *x*-ray plates taken ten or twelve weeks afterwards, showed a slight angulation and slight anterior bowing but there was no shortening.

The Management of Fractures of the Femur.—Dr. JOHN J. MOOREHEAD made this presentation, which he illustrated with lantern slides. He said that the treatment of fractures of the largest bone in the body imposed upon the surgeon in civil life the largest responsibility, demanded the maximum of initial and subsequent care; indeed, fracture of the femur was the high mark in major surgery in the field of fractures, a field in which deformity and disability were supposed to be inevitable. Practically speaking, fractures of the femur could be classified as they occurred at the articular ends and in the shaft, thus giving three zones of incidence. Irrespective of zonal distribution, however, there were certain important considerations determining the method of procedure. First of these principles was the recognition that a fracture was a lacerated wound of bone and periosteum, and that there were always associated lesions of the overlying muscles and vascular and neural vessels. They recognized that the deformity following bony cleavage was due to disturbance of muscular compensation and that a bone was "set" only by "setting" the muscles which no longer maintained their accustomed status as to origin and insertion. Fractures of the femur were further classified into those in which there was displacement of fragments and those in which there was little or no displacement of fragments. Early reduction meant easier and more accurate reduction, and with this in view, preliminary traction was a great aid, irrespective of the treatment imposed later. Lacerated bone, like any other laceration, healed by primary union when the edges were well coapted, thus leading to a minimum of callus; noncoaptation meant secondary union and maximum of callus. They recognized that a compound fracture could be converted into a simple one by mechanical sterilization that aimed to expose the fracture site to vision by the exsection of all bruised or otherwise damaged tissue. This débridement and primary suture they reserved for selected cases; it was not practised in badly comminuted cases nor when the injury was more than twenty-four hours old. The safest procedure in converting any compound into a simple fracture was to resort to primosecondary or delayed suture in which all the steps except suture were taken and the actual suturing was performed between the third and sixth day, when they were assured clinically and bacteriologically of the asepsis of the wound. They recognized that the introduction of nonabsorbable material to act as an internal splint was occasionally necessary, but this should be the last resort even in selected cases. They recognized the danger of applying encircling plaster of Paris casts or other splintage combining the demerits of pressure, hiding of the part, and rendering joint motion and massage impossible. For this reason fracture of the neck of the femur was the only displaced variety of fracture subjected to this type of encasement. The choice of operative or nonoperative methods for purposes of reduction depended upon: (1) The physique of the patient; (2) the site, duration, and extent of the fracture; (3) the surroundings of the patient (home or hosptial), and (4) the experience of the surgeon. In the aged, the infirm, or the diseased, the treatment should be directed more to the general than to the local condition, and he would not impose any added burden by apparatus or forced restraint. For all nondisplaced fractures their method of choice was a plaster of Paris spica for the neck of the femur variety, and molded plaster of Paris antero-postero splints in all others. For displaced fractures the method of choice was immediate preliminary traction in a Thomas splint or adhesive plaster straps with weights until permanent reduction could be made under anesthesia with or without a traction table, at which time a splint plaster of Paris spica was applied. The earlier the reduction the easier and more satisfactory. However, experience had taught that in some cases the primary attempt at reduction was wholly unsatisfactory or was incomplete; hence their rule was to make two attempts before resorting to skeletal traction or open operation. There were certain fractures in which no external method of correction had given satisfactory results, and for want of a better name, these were called "irreducibles," and in these skeletal traction had become the sole resort, preferably by the transfixion method. The use of Buck's extension and allied apparatus had been practically completely superseded by other forms of external traction in which the Thomas, Hodgen, or Blake-Keller splint was used. Apparatus of this kind was very efficient in the majority of cases when properly applied and watched, but had the disadvantage of requiring constant supervision and frequent adjustment, and it was not by any means the method of choice for the occasional user. For very greatly overlapped, for long standing, and for most of the supracondyloid group, the essayist did not believe any method wholly satisfactory unless traction was applied to the skeleton itself and for this purpose there was the choice as between open operative correction or resorting to transfixion, the calipers or the stirrup. The calipers had the disadvantage of slipping, even though penetrating the thickness of the cortex of the bone; this probability was the greater if penetration was just into the margin of the cortex.

as so strongly advocated and employed by Pearson. A further difficulty was that one or both ends of the calipers would extrude if the weights were released for an instant. Because of these difficulties incident to traction by straps or the tongs, preference was given to transfixion in that irreducible group in which operation was the only choice. Open operation was never done unless as a part of the conversion of a compound into a simple fracture. Direct exposure and correction of a fractured femur in a muscular subject, especially if plating or wiring was added, was a hazardous procedure, particularly if the surgeon was unfamiliar with an ultra-aseptic technique in which all hand contact was prohibited. Dr. Moorehead described the technique of transfixion through the condyles for the low supracondylar type of fracture or through the supracondylar ridge of the fracture was higher up. If the condyles were involved, or if there was a wound in their proximity, transfixion could be made through the tibia just below the level of the tubercle. Dr. Moorehead stated that the method was first used by him at the Harlem Hospital in 1913 in a series of some 14 cases. To date there had been one infection of the deeper parts, involving the periosteum and cortex, but this speedily cleared up. There had been no fatalities. The merits of the method were: (1) It required no very great skill, no special instruments, no prolonged anesthesia. (2) It was adaptable for home treatment, or where there were no especially trained assistants. (3) The nursing care was minimized because the patient had considerable freedom, and was virtually in a semi-seated position. (4) The introduction of the transfixer at a distance from the actual site of the fracture did not retraumatize an already damaged area. (5) The safety and certainty of the method made a happy choice by comparison with open operation. (6) It was relatively painless, despite the semblance to a barbarous custom. (7) It permitted inspection of the entire limb and joint freedom. (8) It combined reduction and splintage, and once introduced, required only ordinary supervision. Its demerits were danger of infection of the bone and damage to the popliteal vessels and joint bursae. These were elements to be considered, but with ordinary care could be avoided. The Finchetto stirrup, or the Chutro modification of it, the writer had not found as efficient as the transfixion. Management of fracture of the femur in children less than five years of age was either by the overhead slinging up method of both extremities or by a plaster of Paris spica. Beyond this age the treatment was the same as for similar cases in adults. Any method of treatment of fractures of the femur that did not combine reduction with early massage and motion failed to give the maximum service. Fractures had been too much slighted by the surgeon, and for that reason the fracture field was being encroached upon by orthopedists, who by their training were better fitted for the after care than for the initial care of this kind of traumatic surgery. Dr. Moorehead also emphasized the great need for standardization and uniformity in fracture work.

Dr. REGINALD H. SAYRE stated that if there was anything that had struck every one as to the effect of the war on surgery it was the marvellous change in the treatment of fractures. He thought the older men would agree that prior to the war fractures were not treated as intelligently or as well as they were forty years ago, in spite of their having a great many advantages which their elders did not possess. It had been very interesting to him to see how fractures became very vitally interesting when the war came on. When they had classes of surgeons from the army to teach they found that they could not allow the treatment of fractures to go along in the haphazard way it had been doing: these surgeons had to be shown some kind of results. As they knew, the results in fractures, as shown by Walker's report, were anything but desirable. It had come to be the custom for the visiting surgeon to leave fractures for the junior to treat. The visiting surgeon was too busy removing gallbladders, performing abdominal operations, and operating on brain tumors, so that the man who slipped on the ice and broke a bone had rather a hard time of it. He agreed with what Dr. Moorehead had said. One remark reminded him of a hot argument his father and Dr. Hamilton had had at Ann Arbor, a number of years ago, when his father took the stand that Dr. Moorehead had taken, while Dr. Hamilton held that it was the rule to have deformity and shortening following fracture of the femur. His father said that there should be a copy of Dr. Hamilton's book containing this statement in every court house, in order to protect physicians against malpractice suits, but Dr. Hamilton should write another book for the patient's benefit, showing that it was not necessary to have such results if the physician took the bother to look after him.

Dr. JOHN B. WALKER said that if the majority of cases could be shown with the same favorable results as were obtained in the two cases shown this evening they might feel well satisfied with their methods of treating fractures of the femur, but the trouble was, as Dr. Sayre had said, that the average man had not been interested in fractures. Dr. Walker had been interested in studying and following up the results of these fractures during the war, and while there were a number of results equivalent to those obtained by Pearson in the British army, the best series of cases in the A. E. F. were by Dr. Bulkley and Dr. Blake. Similar results could have been obtained by other surgeons had they given the same attention to the subject as Dr. Bulkley and Dr. Blake.

Dr. WHITE said the discussion this evening was hardly complete without something more being said in reference to open reduction methods and methods of treating irreducible cases by surgical interference. He thought the great difficulty they had in uniting and fixing fragments came from the fact that while introducing screws, plates, etc., the fragments were likely to slip and become separated. He had devised forceps for holding the fragments in place while they were being screwed or plated. One of these was for use in fractures of the femur and the other for fractures of the humerus. They were so constructed that they were out of the way while one was doing the work. These forceps he demonstrated by means of lantern slides.

Dr. H. H. M. LYLE said the paper was clear, concise, and contained a great deal of information. The battle mortality from fractures of the femur was difficult to follow; he thought, however, it was something over 30 per cent. The deaths among the men returned to England with this injury was something over 39 per cent, so there was no question but that lacerated fractures were a very serious proposition. Accidents had happened in using the Pearson calipers from loosening of the arms of the calipers. That could be avoided by adjusting an elastic band on the calipers so that they could not spring apart. Another point was that iodine should never be applied so that it came in contact with the Steinmann pin, because it eroded the pin, making it difficult to remove it without causing injury In removing the pin he always used a local anesthetic. He had seen bad results from the use of the stirrup, such as gangrene of the os calcis, and necrosis of the tendo Achilles.

Dr. KENNETH BULKLEY congratulated Dr. Moorehead in that he had covered the ground very thoroughly and had given a very excellent exposition of the subject, and Dr. Armstrong and Dr. Worcester were to be congratulated on their excellent functional results. Their cases had been treated by the methods advocated by the school which Dr. Lyle had just mentioned, whose chief aim was function. There were a number of points in the paer to which attention might be directed. The first was the question of reduction and immobilization. We had all been taught that in fracture of the femur the first thing was to reduce the fracture and the second was to immobilize it. At the present time we never attempted reduction and never immobilized the fracture. We now tried to overcome angulation and overriding by gradual traction, heavy at first and lightened later. The Hawley table never should be used except in fractures around the neck of the femur. It was difficult to try to pull out a markedly overriding fracture in a few minutes, and it was dangerous. Traction above the knee was useless. Below the knee it could be used only with the knee extended.

This latter was the type of traction the English used in the early part of the war, and while the results anatomically were good, functionally they were very, very bad. He had seen a good many men treated in that way who had a relaxed knee joint and loss of flexion, the flexion being reduced to 10° or 15°. In moving the knee, it was not a question of the amount of motion at first; the important point was that there should be a little motion at first and later the degree of motion could easily be increased. The boy that was presented this evening did not at first have the full motion that he now had. The amount of motion might be greatly increased if the double knee splint is used. So far as open reduction was concerned, he thought it was now almost never necessary. There was only one indication for open reduction, and that was if after a sufficient amount of traction there was no over-riding and there was a displacement equal to the thickness of the bone. This was pathognomonic of muscle interposition. As for the army ice-tongs, they had too sharp points. A second difficulty was that they were not made so that the two arms of the tongs were parallel. The two points must be absolutely parallel when in place. The distance between the points when the arms were parallel should be about 7 cm., such an interpoint distance fitting most adult femurs.

Dr. BYRON C. DARLING said he thought that the *x*-ray man ought to cooperate more in the treatment of fractures because he saw the end results. "The end results were as a routine nowhere near what they ought to be. From the *x*-ray point of view fractures are divided into two groups, namely, those that need reduction and those that did not need reduction. Those that did not need reduction showed good results, while those that needed reduction did not often show improvement of alignment and reposition, especially overriding fractures of the long bones, except when they have a man like Dr. Moorehead to look after them. The problem was that of traction and not anything else. The Steinmann nail gives strong traction. Other methods also gave it, but not without compounding the wound, and not without cutting through the skin, introducing the serious element of possible infection. Every hospital treating fractures should have connected with the *x*-ray department a fracture room equipped with fracture tables that would allow fluoroscopy, and a plate or print without disturbing the reposition of the fracture. This checked up the position before splints or casts were applied, finishing the task as far as possible at one operation, not allowing, as too often happened in the routine, days or weeks to elapse between attempts at reduction while callus was forming and tissue repair was taking place. The earlier the fracture was replaced the better and easier. Anatomical reposition, which hastened union and insured function, was the goal; but one should never open operation or introduce nails or ice tongs, except as bloodless methods failed. However, weeks and months should not be lost by waiting for the unlikely, but if one must interfere by such methods, it should be done at the earliest possible moment. To accomplish this result there must be a combination between the *x*-ray man and the surgeon. The fracture should be reduced within the first twenty-four hours, and kept there. The subject of fractures was, of course, in for a thorough review. Dr. Moorehead's results were good and others have obtained good results, but they had accomplished this after hard work and good judgment. The introduction of metals was as a rule bad. Once in a while a bone tolerated a foreign body, such as a plate or nail, but as a rule they become loose foreign bodies. The ambulatory splint that would hold the traction when it was once obtained and would allow the patient to get up had been advocated, but he had not seen surgeons make enough use of them. The idea of an ambulatory splint and massage to the muscle and joints was most attractive."

Dr. WORCESTER said that on the line on which Dr. Moorehead had spoken so nicely, and which was a plea for using suspension and the Gatch bed, a suspension could be rigged up with the Balkan frame that was very effective. He thought that active motion which was the important part could be much better carried on by some form of suspension. Another point he wished to mention was with reference to making two attempts at skeletal traction. At Bellevue they were using skeletal traction immediately, and he could not see the need of two attempts. They used the Steinmann pin as a last resort because they found that they got bad infections from it. In using the calipers they had had no difficulty with the tongs slipping.

Dr. WILLIAM H. STEWART said that he was particularly interested in diagnosis by means of the *x*-ray. He had made some interesting observations by this method in cases of fracture of the femur while they were under treatment which seemed to show that it was very difficult to reduce a fracture in the middle or lower third of the femur and maintain the reduction. Before Dr. Moorehead went to France he had been treating these cases by means of traction on a drill passed through the lower fragment well below the line of fracture; by this means the reduction had been good, and it was maintained. Never saw but one case showing any serious irritation from the drill, and that one showed marked periosteal production along the shaft. Since Dr. Moorehead's return he had been treating his cases with various means of extension without skeletal traction, and his results were not nearly so good, most of the cases showing overlapping and angulation. From his experience fractures of the middle third of the femur which could not be reduced and maintained by simple traction should be treated by the open method. Disturbance of Nélaton's line could not always be relied upon as indicating a fracture; the speaker had also observed impacted fractures of the neck of the femur which did not show any disturbance of this line.

Dr. MOOREHEAD, in closing the discussion, said he was glad Dr. Lyle's views coincided with his, for he apreciated the value of Dr. Lyle's great experience. As to the iodine dressings, he found so much sloughing without antiseptics that he had tried a dilute dressing consisting of 1 dram of iodine to 1 pint of water, and with this there was not so much sloughing. Dr. Bulkley had advised against the use of the Hawley table, but he thought the Hawley table ought to be used as a method of gradual traction. One should not apply the traction in such a way as to produce a sudden reduction, but should take thirty to forty minutes to effect the reduction. In using the Hawley table as many minutes should be taken for the reduction as it took days by more gradual traction. Dr. Worcester asked why two attempts at reduction were made. The reason was that he shunned to do anything in an operative way if it could be avoided, so they made the two attempts before resorting to even transfixion or calipers. As to what Dr. Stewart had said of this type of treatment, his cases lately had been fracture of the femur in children and his idea was as to what methods were applicable to fractures in children. He found that he got the best results by the overhead slinging up method of both extremities or by a plaster of Paris spica, when the children were under five years of age. In the group of irreducibles, only open reduction or direct skeletal traction would bring about the desired result.

Complete Bone Surgery Outfit.—Dr. C. H. MASLAND of Philadelphia gave a demonstration of the many ways in which these electromotor-driven instruments could be used to advantage in bone surgery. Bone grafts, inlays, and pegs could be cut to a nicety. Dr. Masland expressed the opinion that bone would be used much more extensively instead of metal plates and other foreign bodies in the surgery of the future.

Radium Therapy in Uterine Cancer.—Barnaud cites a series of thirty-two cases treated by hysterectomy, of which eleven survive after an interval of from five to ten years, free from relapse. He therefore does not think that radium therapy should supplant operative treatment. The technique of the former is not yet complete, but the immediate results of radium are pronounced. Fully operable cancers should be extirpated and here secondary radium may be tried, but is not to be regarded as indispensable. The resource should be reserved for the inoperable case and the relapse.—*Journal de médecine et de chirurgie pratiques.*

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

CONNECTICUT STATE MEDICAL EXAMINING BOARD.

November, 1919.

(*Continued from page* 42.)

HYGIENE AND MEDICAL CHEMISTRY.

1. Upon what factors is the self-purification of water in streams dependent?
2. In what way, and to what extent, may ice be a source of danger to health?
3. What should be the duties of a medical inspector of schools?
4. What measures should be advocated to reduce the prevalence of infection in sleeping cars?
5. What would be your advice in the prophylaxis of influenza?
6. What are opsonins? What does the term "opsonic index" mean?
7. Discuss the prophylaxis of rabies.
8. Describe some of the proper means for sewage disposal in rural communities.
9. Give a brief description of Ehrlich's side chain theory of immunity.
10. What does the term "phagocytosis" mean, and what is its relationship to immunity?

MATERIA MEDICA AND THERAPEUTICS.

1. Write a prescription containing any two drugs (except sodium bicarbonate) commonly considered of value in flatulence. (Do not abbreviate.)
2. Write a prescription for an ointment to be used in a case of simple scabies. (Do not abbreviate.)
3. State the average adult dose, method of administration and indications for the use of any two of the following drugs: Liquor potassii arsenitis; tinctura aconiti; physostigminæ salicylas.
4. Describe the action of large doses of aconite on the heart and circulatory system.
5. Describe the physical and chemical properties of quinine sulphate.
6. Describe the treatment of epilepsy (Grand Mal) in a girl 14 years of age who for the past 4 years has had occasional convulsions with increasing frequency and severity without apparent cause. Convulsions now occur on an average of one each week. No history of trauma. Physical examination including Wassermann test is essentially negative.

7 and 8. Outline your treatment of the following case. A married woman of 46 consults you because of occipital headaches, nervousness, insomnia, and weakness from which she has suffered for three years. Prior to this she has always enjoyed fairly good health and has had no serious illness except occasional attacks of tonsilitis. She has never had "rheumatism." She has had no children and no miscarriages. Menopause at age of forty. Her husband is and always has been well. Her father died at age of 55 of heart disease, her mother at age of 48 of pneumonia. No brothers and sisters. On examination you find that she is well developed and nourished but rather pale. There are several unfilled cavities in the teeth and evidence of slight Riggs' disease. The tonsils are not enlarged, but ragged and congested. No enlargement of the thyroid gland. The arteries are palpable but apparently not tortuous or calcareous. There is slight hypertrophy of the heart and accentuation of the aortic second sound. Rate and rhythm normal. Blood pressure S. 190, D. 110. No edema of the extremities. Eye grounds, reflexes and other physical signs negative. Urine 60 ounces in 24 hours; night specimen 32 ounces, specific gravity 1,012; day specimen 28 ounces, specific gravity 1,015. No albumen or sugar in either specimen. Microscopic examination seven or eight hyaline casts (centrifuge). Wassermann negative.

9 and 10. A well-to-do merchant, 47 years of age, 5 feet 7 inches, weighing 180 pounds, consults you because of polyuria. Except for this symptom which he has noticed for six months he has always been well and has been temperate in his habits. His physical examination is negative. You find 2 per cent. of sugar (no acetone or diacetic acid) in his urine on three successive days during which time he has been on his usual diet which has been that of an average man. After twenty-four hours of absolute starvation he becomes sugar free. Outline the further treatment of the above case.

PRACTICE, PATHOLOGY, AND DIAGNOSIS.

1 and 2. (1) Premature contraction; (2) Antigen; (3) Non-proteid nitrogen; (4) Xanthin. Briefly define any three of the above and discuss their practical application to the practice of medicine.

3. Describe the symptoms, signs, course, and treatment of subdeltoid bursitis.
4. What confirmatory symptoms and signs would you look for in a child of seven that you suspected had hereditary syphilis?
5. Describe the gross and microscopic appearance of scirrhous carcinoma of the breast.
6. Discuss the etiology, diagnosis, and course of erythema nodosum.
7. What symptoms and signs would you watch for in a suspected case of acute endocarditis?
8. Describe the symptoms and signs of acute frontal sinusitis.
9. Miss B., 38 years of age, has suffered all her life from periodic headaches occurring every two or four weeks, more especially at the time of menstruation. Except for these attacks she had never been sick and seemed to be vigorous in every respect. Yesterday she seemed as well as usual but went to bed with what was thought to be one of her usual headaches. About midnight her sister, who slept in the same room with her, found her unconscious and in a convulsion. From that time till 8 o'clock A.M. the next morning, when you are called to see her, she had had six general tonic-clonic convulsions (five of them accompanied by complete loss of consciousness) each lasting about a minute and followed by profound relaxation and deep breathing. You find her conscious, but very drowsy and heavy. Physical examination of the chest and abdomen is negative. The reflexes are all somewhat exaggerated especially on the left side and at times Babinski's reaction could be elicited on the left. The pupils were moderately dilated (the left larger than the right) and responded rather sluggishly to light. When conscious she complained of headache and although she had been somewhat nauseated had not vomited. The urine drawn by catheter showed specific gravity 1,014; no sugar and a moderate number of hyaline casts; some with granules or cells adherent. Blood pressure 140-80. Eye grounds not examined. Leucocyte count 16,000 cells, 81 per cent. of which were polynuclears. Temperature 101.3 F.; pulse 100 between convulsions, becoming rapid and feeble during and after them. Bowels were moved by enema and showed nothing of importance. Discuss the diagnosis based on the data as given and state how you would proceed in treating the case.
10. Discuss the diagnosis and treatment of the following case: Miss C., aged 40, is a native of Connecticut. Seven months ago she had a mild attack of influenza followed a month later by jaundice which has persisted and grown more intense. Accompanying the jaundice there has been slight discomfort in the right hypochondrium, but no vomiting, though at times she has been somewhat nauseated. The last half year she has been gradually growing weaker; her appetite has been fair, although she could not eat fats. She has lost 25 or 30 pounds in weight. The bowels have moved on an average of three or four times a day. The stools are well formed and clay-colored. The urine has been dark brown. She has been keeping house for her brother till three days ago. At times she has been extremely tired and has had to go to bed during the day. For the last three months her legs have been badly swollen. Her father died of unknown cause; her mother of typhoid fever. Three brothers and one sister are living and well. No history of rheumatism, tuberculosis, cancer, diabetes or mental disease in the family. Her habits are good, she does not use alcohol. Menstruation has always been regular. Aside from the diseases of childhood she has always been well. Physical examination shows her to be well developed but poorly nourished. The skin is extremely jaundiced having an olive green hue. Pupils equal, regular and

react to light and accommodation. Reflexes normal. The tongue is coated, many of the teeth are decayed. There is no general adenopathy, no enlargement of the thyroid. The pulsation of the carotids is plainly visible. There are numerous fine crackling râles at the right base; otherwise the lungs are negative. The heart is not enlarged; a soft systolic murmur is heard in the fifth interspace halfway between the sternum and the nipple. It is not transmitted. The P_2 is not accentuated, the sounds regular and of good quality. The abdomen is distended. There is no spasm, tenderness or rigidity. The liver is increased in size, extending 6 cm. below the costal margin. It is soft, does not feel nodular, but there is a mass which feels like a distended gall bladder at its lower edge, extending in the right nipple line to the level of the umbilicus. Spleen and kidneys not palpable. There is marked edema of both legs and thighs which are swollen to almost twice their normal size with considerable discoloration below the knees. Pelvic and rectal examinations negative. Temperature and pulse normal. Urine acid, bile tinged, specific gravity 1,014; alb. V. S. T., sugar none. Several hyaline casts. Gastric analysis practically negative. Hemoglobin 85 per cent. R.B.C. 3,820,000. W.B.C. 8,800. Smear and differential count show evidence of secondary anemia only. Wassermann negative.

ANSWERS.

HYGIENE AND MEDICAL CHEMISTRY.

1. *Factors in the purification of waters in streams.*—(1) *Chemical*, the oxidation of nitrogenous organic matter, resulting in its reduction or mineralization; (2) *Biological*, the death of microorganisms through symbiosis, time, and various means; (3) *Physical*, such as dilution, sedimentation, sunlight, etc.—(Rosenau's *Preventive Medicine and Hygiene.*)

2. *Ice as a source of danger to health.* "There should be a system of sanitary inspection of the sources of supply. Ice should not be cut from water known to be contaminated with pathogenic germs, such as the typhoid or tubercle bacilli. If sewage pollution is extensive, there may be frozen into the ice solid pieces containing noxious bacteria. Artificial ice should be made only from water that is suitable for drinking purposes. Ice as a vehicle of disease, however, is far less a menace to the public health than water or milk. Freezing destroys a large majority of the bacteria present, experiments having proved that the majority of typhoid bacilli perish within a short time, and after three weeks of freezing less than one per cent. remain alive. Storage still further eliminates the number of bacteria that survive the freezing process. Houston has shown that simple storage of water in reservoirs reduces the number of bacteria, including fecal bacteria and those of typhoid and cholera. After three months the danger of ice cut from even markedly polluted water is trivial. It is far better, however, to refuse all ice from polluted sources. . . . In transportation ice is less liable to contamination than water or milk, because impurities in the container are not absorbed, and are readily washed off. The great danger of infection from ice lies in unsanitary handling—in the cutting, delivery, and serving. The harvesting of ice is often anything but a cleanly process. The ice-dealer may easily infect the ice with his filthy broom and dirty hands. Finally the ice is often dropped into drinking water by hands dirty and apt to be infected with the discharges from nose, mouth, bladder or bowel of the person handling the same."—(Pyle's *Personal Hygiene.*)

3. *Duties of a medical inspector of schools.* "The object of a medical inspection of schools is not primarily the treatment of diseases, but rather their prevention. One of the principal objects is the early recognition of physical defects such as errors of refraction, imperfect hearing, malformations of the body from abnormal positions, adenoids, enlarged tonsils, and other obstructions of breathing, and sources of inflammation, etc. An important object of the medical inspection of school children is to determine their fitness to enter school and to recognize mental and nervous disorders; also the early recognition of the communicable diseases, and measures to prevent their spread; the supervision of vaccination, and disinfection; the teaching of personal hygiene to pupils and teachers, and the sanitation and cleanliness of the school buildings and its surroundings; the adjustment of the seat and desk, and the medical supervision of the mental and physical work of the child."—(Rosenau's *Preventive Medicine and Hygiene.*)

4. "Before attempting to fumigate the interior of a sleeping car or a passenger coach with one of the disinfectants it is important to close the sashes and all the ventilator openings for the Pintsch gas flames. Much gas will be lost through the open hopper of the water-closet unless that is tamponed. Some cars have a system of ventilating ducts of fresh air entering under the seat or somewhere near the bottom of the car. This must be closed. Formaldehyde gas and hydrocyanic acid gas are practically the only gases which may be used for the treatment of the sleeping car. As these gases lack the power of penetration, all the berths must be opened and all the bedding and other fabric should be removed for steaming or other treatment. Hydrocyanic acid is especially serviceable for the destruction of bedbugs and vermin which frequently infest sleeping cars. After the bedding, hangings, carpets, and other fabrics have been removed from the car, the toilet-room should be given special attention. The drinking glasses, the wash basins and slabs of the washstands, the brushes and combs, the seat of the water-closet, and other objects liable to infection should be washed or immersed in one of the standard germicidal solutions."—(Rosenau's *Preventive Medicine and Hygiene.*)

5. *Prophylaxis in influenza.* Isolation is important; during epidemics people should avoid crowded places, such as theaters, churches, mass meetings, packed cars. People with catarrhal symptoms should be avoided. The laws against spitting should be enforced; and the public should be educated as to the danger of using common drinking cups, roller towels, handkerchiefs, spoons and other implements that come in contact with the mouth.

6. *Opsonins* are substances which act upon bacteria and other cells in such a way that they are more readily ingested by phagocytes.

The *opsonic index* is the ratio of the number of bacteria ingested by a given number of phagocytes in a patient's blood as compared with the number ingested by the same number of phagocytes in normal blood.

7. *Prophylaxis of rabies.* The muzzling of dogs should be strictly enforced; stray dogs should be destroyed; when a person is bitten, the wound should be treated by the actual cautery or by nitric acid; silver nitrate is useless; the Pasteur treatment should be begun early. When a person has been bitten the dog should be kept under observation, or killed under proper control, and a post-mortem made so as to determine whether or not it had rabies.

8. *Sewage disposal in rural communities.* The first requisite is a "protected privy, that is, one where the fecal matter is received in a tight vault so constructed that the contents cannot be reached by flies, insects, rats, hens, or pigs, yet so ventilated as to prevent disagreeable odors, and give opportunity for evaporation of liquids. This necessitates the liberal use of screens around the vault and on the windows and doors, and the use of a self-closing cover for the seat. . . . Privies that are not provided with water-tight vaults, but are so arranged that the fecal matter falls upon the soil, may be safe, so far as water pollution is concerned, if the soil is of proper character and if the privy is sufficiently removed from the house well; but are undesirable for other reasons. No arbitrary rules as to the necessary minimum distance of a privy from a well can be laid down, as everything depends upon the character of the soil, the slope of the ground, the elevation of the natural ground water, and the draught of water from the well. . . Cesspools are holes dug in the ground to receive not only fecal matter, but also, perhaps, sink wastes and water-closet discharges. They are often lined with loose stones to prevent caving, but this permits the liquids to leach into the soil. When the soil is sandy there is no objection to this method of disposal. . . Leaching cesspools, however, should not be located near wells used for drinking

water supplies. . . Ordinarily leaching cesspools should not be constructed in clay soils or in limestone regions, for they are liable to seriously pollute the ground water and are almost sure to overflow. If cesspools are necessary under such conditions they should be made water-tight and treated as septic tanks and the effluent taken care of by subsurface irrigation or some form of land treatment. . . The disposal of the contents is one of the most troublesome questions connected with cesspools. The common method is to spread it upon the land as a topdressing. The work is apt to be done in the winter, and not infrequently when the ground is frozen. Thus opportunity is given for fecal bacteria of human origin to be washed into a well or some public water supply. If spread on the ground during the summer, flies have access to it. If used for fertilizer for crops eaten raw, as celery or lettuce, opportunity is offered for transmission of infection by such foods. The only proper method of disposal for cesspool sludge is by burial or disinfection. In laborers' camps, and in army camps, disposal of fecal matter by cremation is practised with advantage." (From Rosenau's *Preventive Medicine and Hygiene.*)

9. *Ehrlich's side chain theory of immunity.* "This receives its name from its analogy to the benzole ring in chemistry with the accompanying lateral chains. For convenience terms are used that can be applied to formed bodies, although they cannot be demonstrated as such in body juices. In this theory it is claimed that immunity depends upon the presence or absence of 'receptors,' the equivalent of the chemical lateral chains. The normal or fixed receptor is that body attached to the cell by means of which the cell is acted upon by various substances, nutritive or otherwise. Each receptor is supposed to be so formed as to unite with a certain body of a definite character. When the action of the bacteria upon the tissue cells is considered, it is supposed that the poisonous products consist of two portions, the 'haptophorous' and the 'toxophorous' groups. The combination is thought to take place as follows: The haptophoric group unites with a certain definite receptor, and by so doing interferes with the normal function of the cell. At the same time the toxophoric group is able then to act directly upon the cell. If this group is very powerful the cell is destroyed, and if a sufficient number are involved the individual may die. When such a union occurs the receptors are of no further use. It has been found in such cases that in order to get back to the normal the cell will be so stimulated that new receptors similar to the ones destroyed will be formed. As a rule, a great excess of receptors will result, and many of these will be cast forth into the circulation, becoming free receptors. These cast-off receptors are what constitute an antitoxin, and on coming in contact with the toxin molecule, unite with the haptophorous portion and consequently render it harmless. It being attached to a free receptor, it is no longer able to combine with a fixed receptor. In bacteriolysis and hemolysis, or cytolysis in general, conditions in which the destruction of actual cells is concerned, the destruction is brought about in a more complicated manner. Two other bodies than the cells are involved. One of these, known as the complement, is normally present in all serum. It is destroyed by a temperature of 55° C. for one-half hour, and is termed, therefore, thermolabile. The other, the immune-body, or amboceptor, occurs in serum only as the result of the injection into the individual of the definite antigen. In other words, the amboceptor is specific in that it can combine only with that substance which gave rise to its formation. As it can resist heat up to 80° C., it is termed thermostabile. In order that the cell be destroyed the complement unites with the specific amboceptor, which in turn joins with the fixed receptor, and the destructive action then occurs. In active acquired immunity against foreign cells the invaded animal forms large amounts of amboceptor, which, being free within the blood, unite with and destroy the invading cells. If the supply is sufficient, the individual will recover. In passive acquired immunity large numbers of amboceptors in the serum from the immunized animal are directly introduced into the patient, and in this way effect a cure."—(McConnell's *Manual of Pathology.*)

10. *Phagocytosis.* "There are certain cells in the body that have the power of ameboid movement, by means of which they are able to surround and take up bacteria and destroy them. These cells are known as phagocytes. Metchnikoff believes that immunity is the result of the positive and negative chemotaxis (power of attraction) existing between the phagocytic cells and the microorganisms. He divides such cells into two classes: (1) *Microphages*, represented by polymorphonuclear leucocytes; and (2) *Macrophages*, large mononuclear leucocytes, endothelial cells lining serous membranes, and fixed mononuclear cells of the spleen follicles and lymph sinuses. The most active are the microphages, as they have the power of independent motion. When the bacteria gain entrance into the body, the phagocytes are attracted, and they attempt to ingest and destroy the invaders. If the immunity of the animal is marked, many of the organisms will be bound within the cells; if the immunity is slight, few cells will contain bacteria. At one time it was claimed that phagocytes could take up only dead bacteria, but it has been demonstrated that the leucocytes can take up living organisms. As a rule the bacteria are ultimately destroyed, but on the other hand, the phagocyte may be the one to perish, and in this way permit a wide distribution of the invaders. Experiments have shown that the bacteria must be acted upon by a substance in the blood known as an *opsonin*, before the phagocyte is able to digest them."—(McConnell's *Manual of Pathology.*)

MATERIA MEDICA AND THERAPEUTICS

1. *Prescription for flatulence:*
   ℞. Spiritus chloroformi
   Tincturæ cardamomi compositæ aa ʒ iv.
   Misce, et signa:—Take twenty drops in hot water every two hours.
2. *Prescription for ointment in case of scabies:*
   ℞. Unguenti sulphuris ʒ ij
   Signa:—Apply as directed.
3. LIQUOR POTASSII ARSENITIS. *Average adult dose*, three minims. The drug should be *administered* in water, beginning with a full dose, say six minims, and this dose is steadily reduced; it should be taken very soon after meals. *Indications:* Pernicious anemia, leukemia, chlorosis, chronic malaria, certain obscure bone and joint diseases, malnutrition.

TINCTURA ACONITI. *Average adult dose*, five minims. *Administration:* It is best given in a little water every two or three hours; or minim doses may be given every hour until it takes effect. *Indications:* Nervous excitement, chronic nephritis, uremia, eclampsia, to reduce fever.

PHYSOSTIGMINÆ SALICYLAS. *Average adult dose* is 1/60 grain. It is best *administered* in pills. *Indications:* Epilepsy, tetanus, chorea; hypodermically, as a purgative; and locally, to reduce intraocular pressure.

4. *Action of large doses of aconite on the heart and circulatory system.* "If the therapeutic dosage is exceeded, the primary slowing of the heart rate turns rather suddenly into quickening, accompanied by arhythmia, which finally becomes extreme. Toxic doses greatly increase the force and especially the rate of the heart, at the same time rendering it extremely arhythmic. The beats may occur in groups, as with digitalis. The heart finally goes quite suddenly into delirium cordis, and stops. During the earlier stages of this action the blood pressure is extremely variable, according to the varying force of the heart, and the successive stimulation and depression of the vasomotor center. Toward the later stages the pressure drops severely. The cardiac effects are due partly to stimulation and depression of the vagus and accelerator mechanisms, but mainly to direct action on the cardiac muscle; the excitability of the latter is greatly increased, somewhat as with digitalis."—(Sollmann's *Manual of Pharmacology.*)

5. *Properties of quinine sulphate.* It is a light, white substance, occurring in silky, flexible crystals or as monoclinic needles; it is odorless, but has a persistent and very bitter taste. It is soluble in about 700 parts of water and in about 100 parts of alcohol. It is more soluble in acidulated water. On exposure to the light it becomes discolored. A saturated aqueous solution is neutral or slightly alkaline to litmus, and when

acidulated with dilute sulphuric acid it develops a blue fluorescence.

6. *Treatment of epilepsy.* "In all cases, upon the development of fits the most painstaking care must be exercised to discover any possible source of irritation, since in the early stages removal of local irritations may lead to mitigation if not cure of the disease. The best possible hygienic conditions must be secured. The child should not be forced to keep up in studies with others better endowed. Excellent results have been achieved at epileptic colonies where the patients are taught some interesting and useful manual occupation. The diet should be light, nutritious, and nonstimulating; recent studies suggest the wisdom of reducing foods containing purin bodies (meat, fish, tea, coffee, etc.), and some observers believe in the desirability of reducing the sodium chloride intake. The bowels should be opened regularly and thoroughly; colonic flushings seem sometimes to be of service (lessening intestinal autointoxication?). The epileptic seizure requires no special treatment, aside from care to prevent the patient's injuring himself; a mouth gag or similar contrivance between the teeth to prevent his biting his tongue (usually impossible, on account of the brevity of the attack); and loosening the clothing to facilitate breathing. On the whole the best medicinal treatment still seems to consist of the use of the bromides, despite some opinions to the contrary. Any of the bromides may be given, although perhaps the mixed bromides secure the best results." (Kelly's *Practice of Medicine.*)

7 and 8. The condition is one of arteriosclerosis, with chronic interstitial nephritis. The teeth and pyorrhea should be attended to by a competent dentist. Free and continued elimination is indicated, and the patient should receive small daily doses of magnesium sulphate, and Basham's mixture and strychnine sulphate 1/40 grain, thrice daily. Outdoor exercise, such as walking about a mile, should be indulged in daily; the patient must wear warm clothing and avoid chills. Rest is also essential, and the patient should sleep about eight or nine hours in each twenty-four hours. The diet should be mainly of vegetables, fruits, cereals, milk, etc.; this should be continued for about a month, and its effect on the blood pressure then noted. Two or three times every week the patient should receive a warm bath (about 102° F.) before retiring for the night; this should be followed by brush friction.

9 and 10. The diet must be carefully regulated, and explicit written directions must be given to the patient. The carbohydrates must be limited, the diet consisting of proteins and fat; the tolerance for carbohydrates must be built up and increased, and a sufficient number of calories must be supplied. With many patients the gradual withdrawal of carbohydrates is tolerated better than their sudden restriction. The percentage of sugar in the urine when the patient is on a general diet is first to be calculated, then the amount on a sugar-free diet, and then the quantity of carbohydrates which can be given without glycosuria appearing. Recently the *starvation diet* of Allen and Joslin has been recommended, but the details of this method are too lengthy for insertion here. Care must be taken lest a diet which is too exclusively nitrogenous should throw an excessive strain upon the liver and kidneys. As a general rule, diabetics *must not take:* Liver, sugars, sweets or starches of any kind, wheaten bread or biscuits, corn bread, oatmeal, barley, rice, rye bread, arrowroot, sago, macaroni, tapioca, vermicelli, potatoes, parsnips, beets, turnips, peas, carrots, melons, fruits, puddings, pastry, pies, ices, honey, jams, sweet or sparkling wines, cordials, cider, porter, lager, chestnuts, peanuts. In every case the diet list must be prepared for the individual patient, The general health must also be attended to. The patient should lead a quiet life, free from worry, take gentle exercise, bathe daily in warm water, and only take drugs when indicated. The most commonly used drugs are codeine, morphine, strychnine, arsenic, and cod liver oil. For the extreme thirst citrate of potassium or lemon juice with water may be given.

PRACTICE, PATHOLOGY AND DIAGNOSIS.

1. and 2. *Premature contractions* "are defined as responses of the heart to new and isolated impulses formed in the musculature; they are contractions which occur before the anticipated time and which consequently disturb the rhythmic movements of the heart. Premature contractions are of two chief kinds: some arise in the ventricle, others in the auricle. Arising in the auricle, they spring, not from the pace-maker, but as a rule from some extraneous point. The premature auricular contraction is followed by a similar beat in the ventricle which, therefore, repeats the auricular irregularity. The premature ventricular contraction, on the other hand, does not disturb the sequence of auricular contractions; the disturbance is confined to the ventricle. . . . Premature contractions are seen in early life as accompaniments of infectious diseases (diphtheria especially); in later years they may be associated with almost any disease, infectious or otherwise; they are occasional phenomena in a large proportion, if not the majority of healthy adults. When numerous, their incidence is greatest in heart disease." (From Osler and McCrae's *Modern Medicine.*)

Antigen "is any substance which, when injected into a suitable animal, has the power of generating an antibody. Practically all pathogenic bacteria and pathogenic protozoa act as antigens; many albuminous bodies, such as the venoms, the enzymes, and bland proteins, may also act as antigens. As the reaction is specific, it is possible to determine whether a particular microorganism is the true cause of a disease or not. Thus, Bordet was enabled to satisfy himself that the bacillus which he isolated during the early stages of whooping-cough was the true cause of that disease, as it gave the reaction of fixation with a specific antibody. On the other hand, if the antigen is known, the diagnosis may be made through the reaction of fixation, as in the case of syphilis and the Wassermann reaction." (Rosenau's *Preventive Medicine and Hygiene.*)

Non-proteid nitrogen is the nitrogen contained in organic substances of a less complex structure than proteid; it includes urea, uric acid, creatinin, etc. The determination of the non-protein nitrogen in the blood is used in the diagnosis and prognosis of uremia, nephritis and allied conditions. An increase in the non-proteid nitrogen in the blood would indicate an impending uremic attack and the advisability of giving a diet low in proteids.

Xanthin is, chemically, dioxypurin; and as uric acid is trioxypurin, xanthin may be considered as uric acid less one atom of oxygen. There is a very small amount of it found normally in the urine; it is sometimes found as the base of renal or vesical calculi. If it occurs in excess, there is probably excessive formation of purin bodies within the body, or else lack of an oxidizing enzyme which would convert it into uric acid.

3. *Subdeltoid bursitis.* "Pain is a constant symptom and is especially annoying at night, the patient being unable to get into a comfortable position. Local tenderness may be elicited over the anatomical limits of the bursa and is usually most marked over the great tuberosity, just external to the bicipital groove. Demonstrable effusion is not uncommon but is disguised by the overlying tissues. If left to himself, the patient tends to maintain the limb in the sling position and resists movements in the direction of abduction and rotation. In the treatment of this affection the arm should be maintained at a right angle to the body, the upper arm being rotated inward. When pain permits of it, movements of the arm and massage are persevered with. In neglected cases, when adhesions have formed and the shoulder is fixed, it may be necessary to break down the adhesions under an anesthetic." (Thomson and Miles' *Manual of Surgery.*)

4. *In a child aged seven years, suspected of hereditary syphilis,* there would probably be found Hutchinson's teeth (notched upper central incisors); interstitial keratitis may be present, also deafness. Osteoperiostitis, arthritis, and dactylitis are suggestive of the condition. Gummata may appear, and the palate and nose may be necrosed or ulcerated. A Wassermann test should be made by a competent laboratory worker.

5. *Scirrhous carcinoma of the breast.* "This is usually met with in women between the ages of thirty-five and fifty, and it often begins while the patient is still menstruating regularly. It sometimes occurs in patients below thirty. The most common site is the upper and outer quadrant of the breast, but it may occur in

any part of the gland. Sometimes there is more than one nodule in the breast. In its early stages the condition is quite painless, and the existence of the tumor is usually discovered accidentally. In some cases indrawing of the nipple or dimpling of the skin over the breast first attracts attention. It is often noticed that there is a difference in the level of the two nipples, that of the affected breast being at a higher level than the other (Watson Cheyne). As the disease progresses the patient experiences a dull, aching pain, with occasional sharp twinges shooting through toward the shoulder, up into the neck, or down the inner side of the arm. On palpation, a more or less circumscribed and fairly well-defined tumor of stony hardness may be felt in the substance of the breast. Not being encapsulated, it cannot be moved apart from the breast. When firmly pressed against the chest wall with the flat of the hand the tumor becomes more evident, and its stony hardness is fully appreciated. The skin over the growth may for a long time remain free, but, as the disease progresses, it becomes tacked down, and is later dimpled by contraction of the suspensory ligaments of Cooper. When the skin becomes invaded by the tumor it assumes a characteristically coarse and indurated appearance, aptly compared to that of the skin of an orange or to pig's skin. When the tumor is near the center of the breast, it causes retraction of the nipple by dragging on the large ducts. It cannot be too strongly emphasized that the presence of all or any of these symptoms is not necessary for the diagnosis of cancer, and that when there is any doubt the patient should be given the benefit of an exploratory operation. In this variety of mammary cancer, the connective-tissue elements predominate while the masses of epithelial cells are comparatively few in number and small in size. Toward the center of the tumor the epithelial clusters are compressed by contraction of the newly formed fibrous tissue, and undergo fatty degeneration. Toward the periphery the stroma is less dense and the epithelial masses are larger and more numerous. They fill the smaller acini, and, after bursting through the basement membrane, invade the lymph spaces of the stroma. The tissues immediately surrounding the tumor are usually infiltrated with leucocytes. On a section being made through the tumor there is a characteristic creaking sensation as the knife divides the tissue, and the cut surfaces become slightly concave owing to contraction of the dense fibrous tissue in the center of the growth. Toward the center, the section presents a grayish-white, striated appearance, closely resembling that of an unripe pear, and scattered over it there are usually several yellow spots due to fatty degeneration of the epithelial elements. Toward the periphery the tissue is softer, of a bluish or pinkish color, and shows numerous minute hemorrhagic points." (Thomson and Miles' *Manual of Surgery.*)

6. *Erythema nodosum* "is largely observed in youth and early adult life. It is uncommon after the age of thirty. It is met with two to five times as frequently in females as in males. Rheumatism, gastrointestinal disorders, and general nutritive disturbances are not infrequently associated. The disease is usually ushered in with fever, articular pains, malaise, and coated tongue. Soon roundish or oval node-like swellings, varying in size from a hazelnut to an egg, develop over the region of the tibiæ. In some cases the forearms, trunk, and, more rarely, the face are involved. The nodes are rosy red in color, tense and shining, like erysipelas, and exquisitely tender to the touch. At first hard, they later soften, but never suppurate. Their duration is from a week to ten days, during which time they undergo all the color gradations observed in common contusions. In number they vary from about five to twenty. The distribution, tenderness, symmetry, course, and color changes of the lesions enable one to differentiate the affection from bruise, abscess, gumma, and erythema induratum." (Schamberg's *Diseases of the Skin.*)

7. "Occurring, as it does, in the course of some other disease, the subjective symptoms of *acute simple endocarditis* are usually masked by the manifestations of the primary condition, until disturbances of the circulation direct attention to the heart. Increase of temperature, precordial distress, cough, slight dyspnea, and more or less persistent vomiting may be present. The action of the heart is increased and often tumultuous. The carotids throb and there are noises in the ear. As the inflammation progresses, the cardiac action and pulse become less frequent, and venous stasis and more or less pulmonary congestion occur. The attack lasts from one to three weeks. *Auscultation* reveals a change in the character of the sounds (prolongation) and sometimes the development of a murmur corresponding to the affected valve."

In acute malignant endocarditis. "the septic intoxication is manifested by headache, restlessness, delirium of varying degrees, dry coated tongue, sordes on the lips and on the gums, nausea, vomiting, constipation or diarrhea, leukocytosis, irregular fever, rigors, and sweats. The heart's action is rapid, irregular, and weak, and the pulse is compressible. The spleen is enlarged and albuminuria is present. Paroxysmal dyspnea and cyanosis are common symptoms. The patient frequently experiences a sense of impending danger, great anxiety, and terror. The occurrence of embolism is marked by additional symptoms referable to the organ affected. If the brain, rapidly developing palsies with disorder of consciousness; if the kidneys, deep-seated lumbar pains with hematuria or disordered urinary flow; if the spleen, pain and tenderness of the splenic region with increase of temperature record. *Auscultation* reveals the replacement of the normal, booming, muscular, first sound by a feeble, irregular cardiac pulsation. Generally a murmur may be detected, but it is subject to great variations, and may be absent." (Hughes' *Practice of Medicine.*)

8. *Acute frontal sinusitis.* "The symptoms are frontal headache, sometimes severe pain, with nausea and vomiting. Redness and swelling over the sinus and edema of the eyelids. . . When a transilluminator is placed beneath the brow, the light is transmitted better by a large normal sinus than by one containing pus or a tumor. However, the size and shape of the frontal sinus varies so greatly in different individuals that a much more satisfactory result can be obtained by an *x*-ray photograph than by transillumination." (Gleason's *Diseases of Nose, Throat and Ear.*)

9. The case might be diagnosed as one of *uremia*, but this is improbable. *Nocturnal epilepsy* with *status lymphaticus* is also improbable, because the patient's sister had been in the habit of sleeping in the same room with her for some years, and had never known of any similar attack, nocturnal or diurnal. The absence of any previous cardiovascular or renal disease, the normal condition of the heart and blood-pressure, the absence of any history or present evidence of syphilis, make *apoplexy* and *vascular crises* somewhat improbable. *Cerebral tumor and abscess* are possibilities, and cannot be absolutely excluded, but a higher blood-pressure might have been expected; and fundus examination in this event would have shown a choked disc. The leucocytosis gives no help. Lumbar puncture, with examination of the cerebrospinal fluid, is suggested as an aid in making the diagnosis; the presence of the diplococcus of *epidemic meningitis* would settle the diagnosis as one of that disease. Injection of Flexner's antimeningitic serum is indicated. (From Cabot's *Differential Diagnosis*, Vol. 1, where the case (No. 266) is fully discussed.)

10. The case is probably one of carcinoma of the head of the pancreas or of the ductus communis choledochus. The edema in legs and thighs is due to pressure on the inferior vena cava.

The treatment is hopeless. Morphine may make the patient more comfortable.

(*To be concluded.*)

Uncle-Niece Marriages.—This subject has been agitated by the Eugenic Society of Sao Paulo. Coelho quotes authorities and cites cases which make against such unions. Nevertheless there is some opinion which sanctions such unions and the author has sent out a questionnaire which seeks to ascertain the views of medical men pro and con. Two leading medical men received these questions and one replied that he was opposed because a consanguine union doubles any family taint. The inference is that there is a movement on foot to remove this inhibition.—*Brazil Medico.*

THE EVOLUTION OF A CHILDREN'S CLINIC.

CREATING A POST-GRADUATE TEACHING DEPARTMENT IN A MODERN GENERAL HOSPITAL.

BY FRANK HOWARD RICHARDSON, M.D.,

BROOKLYN, N. Y.

ASSISTANT PEDIATRIST AND CHIEF OF CHILDREN'S CLINIC, BROOKLYN HOSPITAL.

THIS paper supplements one published in the *Archives of Pediatrics* for February, 1920, entitled "A Model Pediatric Service for the Modern General Hospital." It sets forth, in a mixture of history and prophecy, the evolution of a Pediatric Dispensary in its progress from the average *toward* (not *to*) the ideal. The fact that a real pediatric seminar, in little, is being built up for the benefit of the men who serve it, is one of the interesting end-products of an attempt to cope with the increasingly difficult and puzzling problem of the dispensary today. Whether or not the individual hospital should thus attempt to become a teaching center for the men who give their time to it, is a fair question for discussion. The dispensary whose hegira is described here, is the outdoor service appertaining to the Pediatric Department discussed in the former paper.

To most of us who have served in one, the phrase "children's clinic" connotes rather a drab, humdrum affair, the fag end of a general dispensary service. It is usually divided into two services, covering alternate days. It is served by a varying number of doctors, who attend when their private practice is not too engrossing. Into it wanders everything medical under the age of twelve or thirteen, except, perhaps, cases which the doorman diagnoses as "tonsils and adenoids," and sends by virtue of his diagnosis direct to the throat department, no matter what else they may be suffering from. Each patient is asked a few questions by the overworked doctor who happens to be present. These may be pretty well expressed by their least common multiple, "What is the matter with the child?" After as much of an examination as the number of cases still to be turned out allows of, the doctor writes down a number corresponding to a mixture in the dispensary formulary, hands it to the mother, and calls out, "Next!" Not very inspiring to either mother or physician, is it? And yet we wonder why busy physicians, whose time for anything outside their own practices is so limited, lose interest after a few months of this sort of thing, get lax in their attendance, and eventually drop out. Instead of wondering why they do not keep on, it is really far more rational to ask why they should stay as long as they do! Probably three reasons will explain the motives of most of the men. One class stays on in the hope that faithful service may at last lead to that greatly-to-be-desired haven, a place on the inside staff. Once here, they may look back at a tiresome ordeal safely passed through—but never to be repeated! A second group desires to be able to say that they are connected with a certain hospital—perhaps to be allowed to bring in their private cases to its private pavilion. A third class, which recruits the constant and every-changing "turnover," consists of men who come with a desire to learn something. These men usually feel, in a few months, that they have gained about as much as they ever will, and that they are giving the institution far more than they are getting from it. And the dispassionate observer is inclined to endorse their verdict. As was recently remarked, in the course of a discussion in the New York Academy of Medicine on this very subject, "It is no longer the clinical assistant that is on probation; it is the hospital!"

When we began to look over the field before attempting to re-create our children's clinic, we found that the average dispensary suffered from some or all of the following defects. Tabulating them seemed to bring our problem out into the open, at least. First, an almost universal defect was a lack of enough men to handle the volume of work presenting itself, on anything but a perfunctory basis, entirely different from the scientific basis on which the ward work was carried on in the same institution. In other words, there was a lack of comprehension of the fact that an ambulatory patient may be quite as sick an individual, and quite as needy of careful study and treatment, as another patient who chances to find himself in bed. This shortage, of course, precluded the proper studying of every individual case as a matter of routine policy, through sheer pressure of work ahead. Only the occasional specially interesting case received the careful attention and study that is the portion of every ward case. The man who catches a glimpse of some fifteen or eighteen mothers waiting in the anteroom, accompanied by an equal number of youngsters, is not going to spend much of his precious hour or two in tracing out the border of a heart, or making a Schick or a Pirquet. The volume of work ahead that must be turned off by him alone is too great to allow him to devote the adequate time and attention to the average case. As a corollary to this, admissions to the hospital from the dispensary are not properly worked up. Data that could have been obtained at the time of the initial examination by the clinical assistant from some relative who happened to be with the child, may not

be available to the house admitting officer later. Another corollary is that opportunity is lacking for conference with other men over interesting points as they come up—a most fertile source of inspiration and education. Of course, in such a state of affairs, no definite instruction or training can be given the clinical assistants. In other words, there is allowed to exist a sort of catch-as-catch-can policy, that assumes that any doctor is fitted by his ordinary training to treat the diseases of infancy and childhood. This, of course, is in itself a contradiction of the right of pediatrics to exist as a special and separate branch of medicine.

Again, we noted a lack of proper provision for enough men to do the work well, even should enough have appeared at once, by any rare chance. So that if, for instance, one more man chanced to arrive at the clinic than there was desk room for, he (or one of the men there before him) quickly made good his get-away, on the plea that there was not room enough for him to work.

Another grave count in the indictment against the average dispensary, had to do with the totally inadequate records kept. No opportunity seemed provided for the taking of histories with any degree of completeness and care, such as is assured when once a patient appears for admission to the wards of any hospital worthy the name. Almost as great a lack existed of any careful recording of complete physicals that might have been made. Although we knew that many men who work in the clinics make careful and complete physicals, yet there was little evidence of this shown by the cards consulted. The outstanding positive findings were recorded; but the negative points were rarely made, so that while one might assume that symptoms and signs had been looked for and not found, there was no way of knowing this for certain. The records, in short, no matter how good might have been the histories and physicals they purported to record, were absolutely valueless for the purposes of any future statistical study. And, letting alone any thought of future case studies, they were not nearly so valuable as they might easily have been made, for the actual conduct of the cases from day to day, which was obviously all that the makers had had in mind.

As against this lack of the useful in the records, was the loss of valuable time and the waste of valuable effort, in the multiplication of records of a single individual, wherever such a one had been referred from one department of the dispensary to others, as so often has to be done. For instance, a medical pediatric case referred to the dental clinic for extractions of carious teeth, to the nose and throat room for examination of the ear, nose, or throat, or for possible tonsillectomy, and eventually admitted to the hospital for some intercurrent disease, would appear four different times as a new case; and, had it been gone over carefully each time, would have presented four complete records. None of these departments would have received any information, except perhaps a bare diagnosis, from any of the departments that had dealt with the child before. Hence an enormous amount of "dead" or inactive material clogged the files.

A serious handicap, under which, fortunately, we did not suffer, was the fact that it was rare that a clinic had anything like the ready access to the pathological and radiological facilities available to the indoor service. The fact that our own dispensary had long enjoyed this was one of the great points in its favor, as compared with the average.

Another thing that greatly interfered with the development of interest in the work, and the advancement of real study by the men, was the fact that ordinarily there was no further subdivision of cases into classes, departments, groups of diseases, or ages, after once they had been assigned, by the man at the door, to the children's room. Everything was taken in rotation, according to the order in which the patients chanced to enter the dispensary. Thus, no opportunity existed for comparing methods and results in a series of similar conditions. As Charles Hendee Smith said once, in demonstrating his model children's clinic at Bellevue (as truly a model for this kind of work, as the Babies' Hospital is for an indoor service): "When you begin to group cases into classes, you can't help learning something about them!"

Perhaps the greatest, most vital lack of all, was the almost total absence of any life-giving relationship between the wards and the dispensary. It was as if a limb were trying to exist separated from the parent trunk. There was no inducement for the clinic man to send his cases into the house, because he lost sight of them completely upon their admission to the wards. Even if a case should come back to him on its discharge from the hospital (as was only occasionally the case), he had no way of knowing what had taken place during the time of treatment in the ward, other than the frequently inaccurate or mistaken notions of the mother. The fact that no matter how carefully a case was worked up, no trace of this, further than the mere diagnosis, ever accompanied it to the house, discouraged such careful effort, even in the infrequent event of there being time and opportunity for it. On its discharge from the hospital, again, unless the interne happened to be sufficiently interested in a child's future welfare to write a personal note to one of the clinical assistants (none of whom he might know, even by sight), it must be picked up practically as a new case, without any knowledge of what had been learned about it in the ward or in the laboratory, and without any indication of what the attending considered a proper line of treatment for its future management.

When it came to grappling with our own problem, we took up first the question of increasing our staff—or, rather, our effectives. For we had men enough, theoretically, for each day; and yet, owing to irregularity of attendance, one man a day was our usual attendance. The first thing we did was to try to make the service so attractive that the men would feel that they could not afford to stay away. And the first measure that suggested itself, was that of inviting them to make rounds in the children's wards, whenever possible. This, of course, entailed both faithfulness and punctuality upon the attending, whose coming was now awaited by several men, at the scheduled time. It also meant a little juggling, and occasional filling in as substitute, on the part of the chief of clinic, in order that the work of the dispensary should not be interfered with, or the patients made to wait unduly. For with improved attendance on the part of the doctors, a clinic

always grows by leaps and bounds. Another innovation that made the service even more popular, consisted in granting to the men the privilege of following through in the wards, under the direction of the attending, any cases that they referred to the hospital from the clinic. Needless to say, the men on the inside gained as much from the increased interest of the cases so referred, as the clinical assistants did from the opportunity of studying in the wards the cases that they had been treating outside. Best of all, the patients received far more intelligent treatment, without any break between their outdoor experience and their ward care; and had their confidence in the hospital and its doctors increased, rather than disturbed, by their transition from the clinic to the ward.

Perhaps the most far-reaching measure that we inaugurated to popularize the work, was the erection of separate departments for the care of special classes of cases. These were placed in charge of men who are specially interested in special lines of work, or who became interested by receiving such assignments. For instance, one of our men was especially desirous of learning something practical about infant feeding. In fact, one of his grievances against the clinic was the fact that he had been set to treating babies, when he knew that he had no real grasp of this subject. A division of the medical pediatric clinic into cases under eighteen months, and those over that age, was made, and he was placed in charge of the former, under the direct supervision of a more experienced man, who definitely undertook to teach him what he himself knew about infant feeding. A special record blank was devised for their use, and it was understood that after a definite period of months had gone by, they were to report on the method employed. Result—a man who had been too busy with outside work to attend the clinic regularly, has found educational advantages so valuable that he cannot afford now *not* to attend his *own* clinic with unfailing regularity.

Our vaginitis class came into being in a different way. We had been sending all these cases away to a distant institution for treatment—how many of them ever reached there, we never knew! A room was loaned us, for one period a week, by the gynecological department adjoining. Here all vaginitis cases are referred to one man, at the end of his regular clinic work. He has become interested in this puzzling subject, and is working on the problem, with the cooperation of some of the gynecologists, whose suggestions he is gladly making use of. It is the tacit understanding that he is to publish the result, in a series of cases, of the treatment that he is working out. Meanwhile, he is ready and willing to discuss methods and experiences with any one interested in this problem; and he is called in by the rest of the men for advice on both private and clinic patients.

Our cardiac class, already existent, was another department where a man might find instruction in a pediatric subject that interested him. The class is in charge of the associate pediatrist of the hospital; for in this hospital, clinic work is not considered "infra dig" for an attending. In fact, it is generally understood that any member of the attending staff who so considered it, would soon be made aware of his error in judgment. As this man was so situated as to receive special cardiac instruction during his army service, we consider ourselves fortunate in having an instructor with abundant clinical material already at hand in this little-understood branch of pediatrics.

But where, you will say, did we find geographical opportunity for all this expansion? Was not our equipment an insuperable bar? We had, to start with, but two adjoining rooms in a busy general clinic, each equipped with desk, chairs, examining table and screen. No external expansion seemed possible. We could, however, use what we had more intensively. This we did by installing an extra desk and chairs in each room, so that two doctors could work where but one had labored before. By a little thoughtful consideration, one examining table serves the needs of two men. When it came to dividing the cases into those above 18 months and those below, one room, with two doctors, was assigned to each group. Our vaginitis room was loaned us, as described above, by our friends of the gynecological department. The cardiac class was accommodated on our lightest afternoon, Saturday, in one of the two rooms, by crowding all the other cases into the other room.

When it came to the establishing of a Nutrition Class, however, which we felt that we needed badly, we had about reached the limit of intensive expansion possible. We had to expand in a new direction. We found, on inquiry, that Saturday morning was a free time for the dispensary building. Permission was readily obtained to occupy the building at this time, and to overflow into rooms adjoining our own, if we chose to do so. This was granted the more readily, inasmuch as there were no fees to be charged and no medicines to be dispensed; so that it was possible to run the extra clinic without the assistance of a single employee of the hospital. All the services required could be furnished by the doctors and the volunteer aides.

A word as to both "rationale" and "technique" of the nutrition class (which grew by leaps and bounds) will show how necessary this added space was. The plan calls for (*a*) an exhaustive history and physical examination, exhaustively recorded, and (*b*) an inspirational appeal, both individual and collective, to both parents and children, to get them to carry out the simple but indispensable details of bathing, eating properly cooked food and eating it properly, taking naps, keeping windows open, having regular bowel movements, etc. The end in view is getting each child to gain weight up to a predetermined normal standard for his height and age. When this is reached, they are "graduated," with due pomp and circumstance.

All this requires from the start certain definite geographical requirements. There must be sitting and working space for enough doctors and volunteer aides to properly examine the children from top to toe, and record their results. As the ages run up to twelve, there must be separate rooms for boys and girls. There must be a room for weighing revisits, each week, and advising them in case of failure to gain, as well as praising them for following out instructions. Finally, there must be an assembly room or waiting room, where the children, and such of their parents as will attend, can be

given the talks and demonstrations that form such an important part of this new line of effort.

Several subdivisions of the Nutrition Class soon developed, as a matter of course. One of them was the Health Class, which came into being in the following way. According to Emerson's definition, the seriously under-nourished child is one whose weight is from 7 to 10 per cent. below an established norm for his age and height. When his children reach their predetermined normal, they are "graduated" out of the Nutrition Class with some small ceremony. We soon realized that, whereas we could soon "graduate" a number of our children, they nevertheless needed guidance almost as much as a number of those whose weights were not so good. The Health Class idea of Ira Weil seemed just the thing. These children are kept under the care of the men in charge of the Health Class, working closely in touch with the Nutrition Class. It is practically the High School Department of the Nutrition Class. The children are notified when they are to return for their periodical re-examinations. Any unremedied defects are kept constantly in mind, and efforts made to have them corrected. New conditions are noted, and may be nipped in the bud, before they have a chance to become fully developed.

A Pretubercular Class is being formed, for the benefit of children whose heredity, physique, and environment make them seem particularly eligible to be grouped under this heading. A man with especially good training in the detection of early signs and symptoms is indispensable for this department. Such a man, when the situation is explained to him, is very easily secured, when he learns that only one day a week is required for the work, and that his participation in it entitles him to participation in the various activities open to the men of the clinic. A Tuberculosis clinic proper has not seemed desirable, in our location. A Lues department already exists, in that the adult G. U. clinic already has its department of arsphenamine therapy for women and children; one of the pediatric men has been especially charged with the matter of "liaison" with this department, and the records of all luetic children will be under his care.

An Infant Welfare Clinic is needed, and is almost invited by the force of circumstances. Our Obstetrical Department has always referred to us its babies, as they were brought in by their mothers returning for post-partum examination. These have never been handled quite satisfactorily, mixed in as they necessarily have been with the sick children of the regular clinic, and pushed into the background by them. As once a week is as often as these babies ever need be seen, and as nutrition is certainly what they are brought in for, as a usual thing, rather than for any form of medication, it is by no great stretch of the imagination that an Infant Welfare Clinic may come into existence as a department of the Nutrition Class. Such a service will increase rapidly, as soon as the mothers realize that a well baby is received as gladly as a sick one; and that we are prepared to render them real service in their problems, rather than mere perfunctory attention. It will present a valuable opportunity for the personnel of the infant feeding class, who are seeing sick babies the other days of the week, to keep themselves familiar with the physiology of the normal infant. If our Obstetrical Department ever establishes a Prenatal Clinic, we shall be prepared to cooperate with them, by means of our own machinery already in existence. Details for this service are already being worked out. An ideal arrangement is to have each outgoing mother and child seen in the hospital by a member of the Pediatric Department assigned to this work, who gives her suitable instructions regarding breast-feeding, supplementary feeding, etc., and tells her when to come to the clinic. Careful discrimination must, of course, be exercised to conserve the interests of the private physicians who send their maternity cases into the hospital.

Now came the ever-puzzling question of the keeping of efficient records of all this work done on the individual child. By "efficient" we mean records that really work enough to justify their existence and pay for their keep. We soon found that there was but one way to handle the record problem, and that was to establish, at least for the children's department, what has been called the individual record room, or central records office. According to this plan any child entering the dispensary for any cause whatsoever, goes first to the pediatric department for a complete examination. This is recorded, together with an equally detailed history taken by a volunteer aide, on rather an extensive blank, uniform for all cases. This was a direct outgrowth of the custom at the Nutrition Class, where several doctors make the examinations, each with a volunteer aide acting as his clerk. This scheme is well brought out by Emerson of Boston. His form is the basis of our own. This record accompanies the child to every special department which he visits for examination or treatment; so that everything known about him is available to any doctor who comes in contact with him, at no more cost than is involved in looking over the record that accompanies him. If he is admitted into the hospital, the record is *loaned* to the house for as long a time as he remains here, and a loan slip corresponding to the record is inserted in the dispensary's files. On his discharge, it is returned to the clinic record keeper, accompanied by a discharge slip, made out by the house pediatrician who has had him in his service on the children's ward. This slip gives the important points in his hospital experience, and makes them available to the dispensary man who is to continue the conduct of the case, together with any suggestions from the attending as to his treatment. The records are available also for the use of properly accredited workers from other hospitals, or from welfare organizations.

A distinct advance has been made along the lines of thoroughness, which is shown both in the attention given the patient and in the character of the records kept. The blank shown here is filled out for each new admission. A glance at this will show both its thoroughness and scope, and the ease with which the results of such a thorough physical examination can be recorded, by checking or underlining, crossing out, and using a double or triple +. In this way, remediable defects are detected that would surely have eluded an examiner, had the patient simply been examined for the symptoms that brought him in. History cards for a number of years back have been incorporated into the new system; so

that many a case that might have been considered a new admission is found to be an old case, returned after a long interim. A full-time social-service worker for the Pediatric Department is an indispensable part of the personnel—one could spend a whole evening dilating upon the ways in which she increases the efficiency of the service, if only one could find anyone, in this day and generation, to whom this fact is not already well known. Not the least valuable part of her services consists in the fact that her follow-up work changes many a casual case into a permanent attendant of some branch of the work. One of the cardinal principles of the clinic is, never to discharge a patient—a return visit, no matter how many days, weeks, or months ahead, is always arranged for. Whatever may be true with adults, we believe that a child should always be under the direct supervision of some agency for the conservation of child health and welfare. In other words, the highest function of such an organization as this is not the alleviation of temporary ailments, but the building up of better boys and better girls—the better men and women of tomorrow. The Nutrition Class serves for this

purpose, in the case of a child who has just recovered from an acute illness, whether he has been treated in the wards or in the clinic. As soon as he is no longer in need of the intensive treatment of the Nutrition Class, he is graduated into its high school department, the Health Class.

A most important part in this dispensary renaissance has been borne by the volunteer aides. A word should be spoken here, as to just what is meant by this term. The head of our Social Service Department, herself a graduate nurse with Red Cross experience, realized that a very valuable potential asset was about to be allowed to dissipate itself, by the demobilization of the young women who had been doing Red Cross work during the late unpleasantness with Germany. She has been able, through her own personality, to attract a staff of these girls, from the best families of the city, many of them of a type to whom the offer of a salary would have meant nothing. Several of them have been assigned to our department, where they have done work of a sort that has greatly increased the scope of the doctors, by freeing the latter from much of the clerical work that had always been done by them in the past. They have not interfered with the strictly nursing work, which is still done by the pupil nurses assigned us from the training school. They do all the filing; and fill in as much of the history blank as is routine, and can be done by a clerical worker quite as well as by a physician, clearing the way for the important questions that the doctor himself must ask, in the pursuit of a diagnosis. Without some such assistance, such history blanks as we use would be, of course, out of the question. In time of shortage of nurses, they may be called upon to help with the simpler nursing procedures. Even more valuable an employment has been made of them, in time of stress, by having them serve as amanuenses for the doctors. The employment of the blank used, which allows of a checking or lining out of many of the words that otherwise would have to be taken by dictation, renders this the more feasible. Prescription blanks with the formulary numbers, transfer slips, hospital admission requests, and clinical pathology blanks, all have to be filled out; and the removal of this work from the doctor to the volunteer aide, enormously increases his medical effectiveness.

To sum up, we have a unified service under one head, the Chief of Clinic. By virtue of his position as Assistant Attending, he brings the clinic into close affiliation with its alter ego, the in-patient service of the childern's wards. They are even more closely bound together by the fact that the clinical assistants are frequently making rounds with the attending, as well as following up the cases that they have sent into the wards. Although unified, it is at the same time highly diversified or "departmentalized" into the following subdivisions:

1. General Medical Pediatric Clinic, daily: (*a*) Infants under 18 months; (*b*) Children over 18 months and under 12 years.
2. Cardiac Class, every Saturday afternoon.
3. Nutrition Class, every Saturday morning. (*a*) Infant Welfare Clinic for well babies; (*b*) Nutrition Class proper; (*c*) Health Class; (*d*) Pretubercular Class.
4. Vaginitis Class, every Friday afternoon, after general clinic.
5. Lues Department (in connection with G. U. Department).
6. Cutaneous Test Department (for vaccination, Schick, Pirquet, protein sensitization, antityphoid and diphtheria toxin-antitoxin mixed treatment, etc.

All these changes, you will say, involve a new conception of the function of a dispensary department. That is exactly the conviction that has gradually been forced upon us. In the days when hospitals were few, and clinical opportunities limited, dispensaries could pick and choose from among those who were anxious to serve their rooms. With the multiplication of hospitals, and the consequent increase in the number of indoor positions to be filled, the dispensary has come to the place where it must offer something of value in return for the services it exacts from its staff. Most hospitals are not as yet prepared to offer financial remuneration to their clinical assistants—but they can, if they will, attract a higher class of men than any they could hire, by offering them real postgraduate opportunities for perfecting themselves in their chosen specialties. This, in short, is what we have tried to do—to create a real postgraduate teaching institution for the men in our outpatient pediatric department. As soon as we realized what this new conception was leading to, we set to work to build up more formal didactic work, in addition to what was already available in the clinic rooms. If the clinical assistants were to be the postgraduate students, it devolved upon the chief of clinic, ex-officio, to provide the instruction. As the representative of the clinical assistants, it is to his interest to see that they are properly taken care of. If they are not, their attendance will become irregular, they will be lacking in dependability, and his results will be poor. We consider it part of his duty to arrange for clinical advantages for the men, as they show a desire to secure special kinds of work. In our own case, the hospital radiologist was approached, and readily consented to give us one period a week for the exhibition and interpretation of radiograms of children. This proved so popular a feature that another period was set aside, immediately following one session of the clinic, at which a man from the otolaryngological department demonstrates conditions of the ear, nose, and throat in children. Suitable cases for teaching are selected from both pediatric an E. N. T. rooms, and held over for this course. A demonstration course in procedures of clinical pathology, especially as applied to children, will probably soon be available. Similar facilities will be provided, or already existing ones expanded, as the men show a desire for them, and a readiness to take advantage of what is offered. Eventually, if a demand for such a thing is found to exist, there will be built up a pediatric seminar that will compare very favorably with the few that exist in this country in connection with postgraduate teaching institutions. Such an opportunity, existing in one's own city, where, without stopping his daily work, a man can ground himself in his chosen specialty, ought to prove a most welcome boon to many a man who could hardly afford either the time or the expense to fit himself otherwise for definite exclusive work in his specialty.

Whether these teaching facilities shall be extended so as to become available to men not on the

hospital staff, whether resident in the city or visitors to it in search of instruction, is a matter for the hospital authorities to decide. At all events, if the greater city ever becomes the great medical center that some of us envisage, there will at least be a working postgraduate pediatric center already existent on this side of the river, which may prove to be a nucleus around which larger things may form and crystallize.

We are leaving behind us—let us hope, forever—the days of the shamefully understaffed clinic, when one man made a mockery of examining and treating twenty or thirty patients in one clinic period. Just what should be the limit of patients seen by one man is still a moot point. The Cornell Adult Medical Dispensary allows but two new cases, and all his revisits, to one man, and turns away all in excess of this. At any rate, we are approaching the time when it will be realized that a dispensary has just as definite a limit to the number of patients that it can treat properly as has a ward inside a hospital. Overloading in the latter case would bring a protest from doctors, nurses, and patients, and, eventually, an order from the Department of Health. Surely the time is coming when the overloading of the former will subject the hospital that allows it to the censure of everyone who comes to learn of it, on the same grounds that we reprobate lodge practise for the private physician. Quick, slipshod work is the best that can be done under such conditions; and the hospital can no more cover that with its ægis, than the private physician of the better sort can afford to allow it in his office.

By a little physical rearrangement, and a little mutual forbearance on the part of the men doing the work, we have utilized our equipment so intensively as to provide working space for as many clinical assistants as we need to handle our cases properly, without increasing the number of rooms occupied. The freeing of the clinical assistants from the pressure of "cases ahead" greatly improves the character of the work done in several ways. It allows of one man's dropping out from the routine work, in order to properly work up a case for admission to the hospital, or do some special examination or test, without halting the work of the day unduly. Liaison with the other departments is greatly improved, and the instructional side of the work greatly enhanced, by the freedom thus allowed for each man to accompany any case, on which he needs special assistance, to the department whose help he wishes, instead of simply referring it there by a slip, and learning nothing about the findings except the bare diagnosis. Each man thus secures as much special instruction in skin, ear, nose and throat, orthopedics, etc., as he cares to ask of the men in these rooms. On the other hand, these men get to know the pediatricians, and become accustomed to reciprocate with their cases; so that the pediatric clinic is enriched at the same time. Time is now allowed for the men to confer over difficult or interesting cases as they come up—one of the most helpful features of outpatient work. They can take turns in making rounds with the chief and seeing their own cases in the wards. Laboratory and *x*-ray help are more frequently sought and more carefully considered. Luetic children, formerly turned over completely to the G. U. department, are now carefully observed throughout their arsephenamine therapy, and returned to our department without a break at the end of the course.

The question might be asked, "What is the effect of such an outpatient department upon the indoor service" "Might be," I say, but never would be asked by anyone who has ever seen the vivifying effect of an active O. P. D. upon its sister service inside the house. The wards are kept full of cases rich in interest, instead of those that chance might otherwise bring in. The men on the wards take a much more careful and painstaking attitude toward their work, knowing that it is at any time subject to review by a number of keen assistants, any one of whom may at any time bring to light an error either of omission or of commission. The whole tone of such a service is lifted out of the rut of routine and mediocrity and placed upon the higher plane always occupied by a teaching institution. A better class of men can be attracted to the staff, because of the class of work and the teaching facilities to be enjoyed; and they are encouraged to do a better grade of work, as well as to publish the results that may justify recording. Last, but not least, the hospital always has in training desirable men for the more responsible positions upon its staff that may from time to time become vacant—men who are interested in maintaining its standards, because they have helped to create them; and jealous of its good name, because it is so intimately connected with their own.

102 Hanson Place.

ELECTROCHEMISM IN THE ETIOLOGY AND THERAPEUSIS OF CANCER.

By EDWARD PERCY ROBINSON, M.D.,

NEW YORK.

It has been aptly put by Matthews that we are "Children of the Sea" and when we apply this remark to our cells we realize the true meaning of the reference. Indeed our cells might be compared to fishes of the sea since they float in, or are surrounded by, a saline fluid, the electro-chemical reaction of which is the basis of this paper.

Eighty per cent. or more of our body weight is water, 20 per cent. then being organic matter, the organization of which constitutes organic tissue—protoplasm—or animal flesh. It must strike the mind rather forcibly, when thinking over the cause of disease or pathological status of the body, that the fluid portion of the body weight must play a greater role in the etiology of disease than the cells whose existence depends on the composition of this fluid; for by all rules of reason a thing cannot be greater than its source. The blood, which is liquid tissue, constitutes the chemical composition of every cell of the body. Therefore, when a cell breaks down there must be something chemically wrong with the composition of the fluids of the body. If goldfish, swimming in a bowl of water, begin to lose their scales we would naturally first think of the quality of the water rather than assume a condition of dyscrasia in the fish. In fact we would first renew the water by a fresh supply before thinking of otherwise treating the fish.

A more tangible illustration of the influence of

environment in the production of morphological transitions may be seen in the case of the brine-shrimp as observed and described by Schmankewitsch. "One species of this crustacean, *Artemia salina*, lives in brackish water, while *A. milhausenii* inhabits water which is much saltier. They have always been regarded as distinct species, differing in the form of the tail-lobes and the character of the spines they bear. And yet, by gradually altering the saltness of the water, either of them was transformed into the other in the course of a few generations." The importance of chemical constitution is seen here and in the language of McFarland, taken from his work, "Biology, General and Medical": "The very important fact that the physical, nutritive, or toxic properties of given substances may be greatly altered by a very slight change in the arrangement of the atoms or groups of molecules may be assumed to be conclusive evidence that a trifling modification in the chemical constitution of a vital substance may give rise to a profound alteration in its physiological properties. This coupled with the fact that the differencies in centesimal composition have proved very inadequate to explain the differences in the phenomena of living matter, implies that a much greater degree of importance is to be attached to peculiarities of chemical constitution than is usually recognized."

Assuming the above to be capable of credence it would seem logical to infer that cells which were once healthy, while living in a certain medium, gradually becoming diseased or cancerous, must owe this pathological state to some change having occurred in the medium.

The medium in which our cells live is the blood and we may consider this fluid under the heading of plasma. The reaction is about equal to the neutrality of sea water and is believed to be nine-tenths of one per cent. strong in sodium chloride. This one particular chemical constituent of the plasma is mentioned here because it is considered by the writer to be the direct cause of cancer and the reasons for so believing were published in the MEDICAL RECORD, September 1, 1917, under the heading "An Hypothesis Regarding the Physiochemical Nature of Cancer."

The view which the writer takes regarding the etiology of cancer is that this disease is purely one of faulty chemism. The fact that any portion of the body may present certain physical manifestations known as cancer is insignificant. The disease is not a local affection and cannot be permanently eradicated by any other means than those directed to a restoration of the chemical constitution of the blood. Most certainly this cannot be done by surgery, radium, or *x*-ray, and experience has demonstrated this to be true from the fact that cancer so treated and apparently cured returns as virulent or more so than it was at first. This statement is revolutionary and it is intended to be so. It is a direct challenge to those who think to the contrary. It is a further challenge to those who are treating cancer by old methods, all of which have been tried and found wanting. It is also an urgent plea to abandon these empirical methods and adopt means of cure which are radical and which prove effectual.

The treatment of any disease, to be effective, must be directed towards the cause. Temporizing with local manifestations is dangerous. The application of radium or *x*-ray in the treatment of cancer is simply temporizing with the disease in that the cause remains uninfluenced. The constitutional dyscrasia cannot be remedied by the mere application of light and heat to a part. Radium has been effective in the treatment of skin cancers but its action is limited. It might oxidize the sodium in the inflamed tissue but it cannot remove this sodium from the fluids of the body, the presence of which is the cause of cancer. If it is justifiable to amputate a leg because of the presence of cancer in the big toe, it is just as reasonable and logical to amputate the leg if the big toe is afflicted with gout. This is the logic of an ostrich, "what it can't see does not exist." The surgeon's logic is just as blind for he amputates once, then a second time. He would operate a third time but the cancerous blood, which he could not see, has killed the patient. All honor to the surgeon, but why adhere to tradition and sacrifice a life when the means of saving it by medical treatment are in the reach of all?

One of the constant accompaniments of cancer is acidosis. In fact the presence of the symptoms of acidosis may be the precursor of cancer. They appear first, the cancer later. Obstinate constipation is almost invariably present in cancer. A decrease in the number of erythrocytes by a million or more, with a low hemoglobin, is the result of every blood-count in a cancer subject. Albumin is seldom absent from the urine. Edema of the ankles, involving the legs, is almost certain to be present and it is not always caused by pressure, for cancer of the breast and edema of the legs coexist. A rough and dry condition of the epidermis is an important symptoms of acidosis; the skin is shed in fine scales. Cachexia may appear later and is in proportion to the hemolysis which is progressive. Therefore, to overlook the presence of the above symptoms and operate on the local manifestations or cancer amounts to nothing more than treating the effect and ignoring the cause.

The treatment of cancer by potassium nitrate was advocated by the writer as late as May 4, 1918, in an article which appeared in the MEDICAL RECORD under the heading "A Plea for the Use of Potassium Nitrate in the Treatment of Cancer," abstracts of which are embodied in this paper.

With the intent to make the treatment of cancer by postassium nitrate clear and understandable we will consider a few recognized facts both chemical and physical and patch them together, and from the whole deduce a working hypothesis. We will begin by borrowing some of these facts from Matthew's Physiological Chemistry: "All protoplasm contains a solution of salts and these salts are of the nature of those of the sea. Michael Faraday found that if a current flows through a solution of sodium chloride, for example, the sodium moves down with the current to the cathode, or negative electrode, and the chlorine moves up against the current to the positive electrode, the anode. Now it is clear that if the sodium moves down with the current it must be positively charged, and the chlorine moving up must be negatively charged, since

only particles with charges on them move in an electrical fluid. When a salt dissolves in water then, as it does in living matter, there are reasons for believing that it breaks, in part, into electrically charged particles which, like so many tiny electrodes,, each bearing one or more electrical charges, float about in the protoplasm and become thereby capable of doing many things. Living matter contains before it is stimulated, then, a large number of electrically charged particles, and it is clear that if in any way an accumulation of positive particles in one place and of negative in another could be produced, and if negative and positive particles had different actions on the vital processes, momentous changes might thus be brought about in living matter." This prediction is capable of verification on the following grounds. If we know the electrochemical nature of two substances we are able to determine their action upon each other. For example, when a solution of potassium nitrate is brought in contact with the circulating medium of the body, which contains sodium chloride, we can,

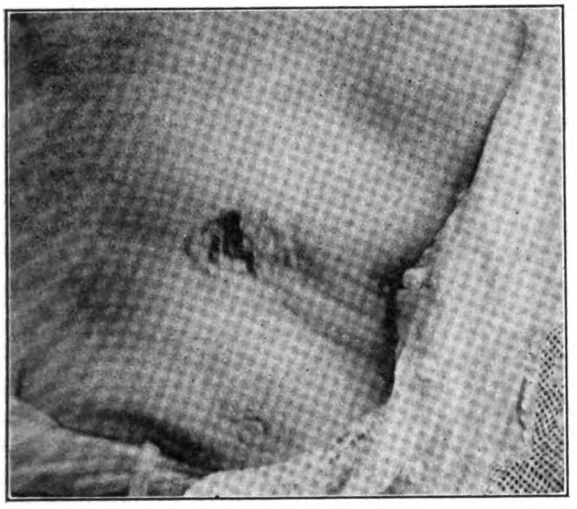

FIG. 1.—Case I. Photograph taken before treatment. The mammary gland is swollen and hard. An area of induration can be felt from the axilla to the median line and as far as the clavicle. The center of the lesion is filled with sloughing tissue. A hard and red rim surrounds the margin of the cancer.

in the mind's eye, imagine electric ions of the positive sodium being bombarded by the negative nitric ions of the potassium nitrate, which by chemical reaction produces sodium nitrate. In like manner the positive potassium ions receive electric charges from the negative chlorine ions of the sodium chloride, producing potassium chloride. The elements. potassium and sodium are electro positive; chlorine, nitrogen and oxygen are electro negative. (Sadtler and Coblentz—"Pharmaceutical & Medical Chemistry" 1918.) According to Matthews, "it may be stated that oxidation in protoplasm is accomplished by such an electrical disturbance"; thus is his prophecy fulfilled, for we see "momentous changes" taking place in cancerous tissue, and this immediately. Theoretically, resolution begins at once because the chemical reaction begins as soon as the two solutions are in contact with each other. Therefore we can assume that the progress of malignancy is also immediately checked, and this is so, for the visible changes in the cancerous tissue and the physical improvement in the patient, generally, justify this assumption; for indeed, the fundamental principle of life, namely, oxidation, has been rekindled and consequently the processes of physiological metabolism are improved and subsequently restored to a normal state.

To quote from the writer's constribution, "A Plea for the Use of Potassium Nitrate in the Treatment of Cancer" in the MEDICAL RECORD, May 4, 1918: "Since the object sought is to replace sodium chloride in the tissues by potassium chloride, and since the end-reaction obtained, when potassium nitrate is administered, is the formation of potassium chloride, the idea will suggest itself quite naturally of giving potassium chloride directly instead of potassium nitrate. But if this is done the potassium chloride would remain in the blood almost entirely, or, if it passed into the tissues, it would not replace or displace the sodium chloride other than in a mechanical way, whereas the potassium nitrate acts chemically by causing actual removal of the sodium elements of the sodium chloride already in the tissues, and their replacement by the potassium elements of the potassium nitrate, at the same time that the displaced sodium elements are removed by combination with the nitric acid elements of the potassium nitrate to form sodium nitrate. The effect of this double reaction is to introduce the potassium in the tissues in the most stable form, namely, potassium chloride.

"There appears to be no other salt which can serve the same purposes as the nitrate. If one should be found later it would probably have thermochemical properties very near those of the nitrate, and the acid radical would probably have as good solvent power for sodium as nitric acid has. There are potassium salts which approach the nitrate in one or the other of these two important respects, but the researches made by the writer have thus far failed to bring to light any other salt that fills the requirements as fully and as satisfactorily as the nitrate."

That displacement of the sodium chloride actually occurs, can be verified by a chemical analysis of the urine. If, for example, a specimen of urine shows the chlorides passed to be 0.50 at the first examination, the next specimen examined after the lapse of a few days will show an increase of chlorides, if the patient is taking potassium nitrate internally. The increase will continue to a certain point and gradually decrease until it has reached a point equivalent to the "threshold valve" (Cushney) of the tissues for sodium chloride. Of course, it is understood that the use of salt in diet should be restricted to a minimum.

In the manufacture of potassium nitrate from Chile saltpetre (sodium nitrate) the double reaction just described is reversed. Sodium nitrate is changed into sodium chloride by the action of potassium chloride, the reaction producing potassium nitrate. Thus any doubt regarding the correctness of the chemical reactions here mentioned in the treatment of cancer is removed and the truthfulness of the interchange of the elements with each other can be corroborated by manual experiment and ocular demonstration. It can be said further that there is not in the entire domain of medical therapeutics one chemical reaction whose opera-

tions, in its relation to disease, is so exact or certain in action as the chemical interchange which potassium nitrate exerts on sodium chloride. In fact there is no known remedial agent comparable with it in the treatment of cancer, not one drug, not one remedy. If there be one, the writer does not know of it.

In the treatment of cancer with potassium nitrate we pass from empiricism of theory to fact. Under its influence sodium chloride is removed from the tissues and the cancer is cured. If salt is not the cause of cancer why should the administration of potassium nitrate bring about a cure by eliminating it? Some one answer this.

The medical treatment of cancer should not be limited to the administration of potassium nitrate alone. The presence of acidosis leads to the assumption that the basic elements of the cells have suffered depletion, since nature, in attempting to neutralize the excess acidity, would in all probability draw a supply of alkaline salts from tissues which might be willing to part with them to restore

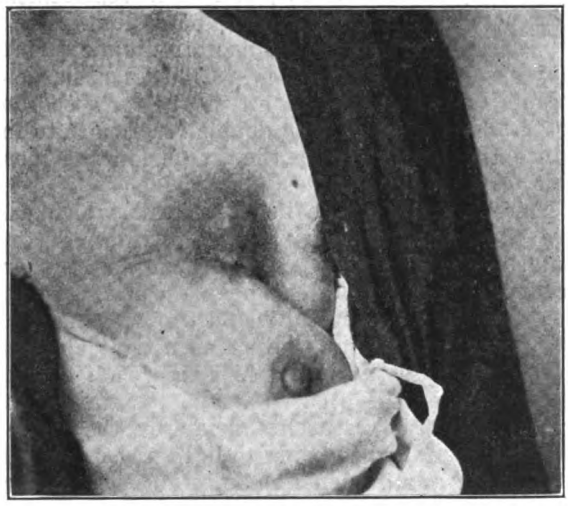

FIG. 2.—Case I. This photograph, taken after the treatment was discontinued, shows the breast reduced to normal. The indurated tissues surrounding the lesion have been absorbed. There is no pain or discomfort and the arm can be moved freely.

neutrality. What these elements might be is purely conjectural, as we have no means of determining their exact nature. We might imagine them to be basic elements, the foundation of the cell, such as magnesium, calcium, iron, manganese probably silicon, etc. Therefore, while displacing the sodium chloride from the cell and replacing it with potassium chloride it would seem reasonable further to strengthen the chemical constitution of the cell by administering some or all of these salts particularly the magnesium, calcium, and manganese. A properly adjusted diet will supply other salts the nature of which, we must imagine, belongs to the entire group of biochemical elements composing protoplasm.

In a very learned article by Dr. Robert Bell, physician in charge of cancer research, Battersea Hospital, London, England, published in the MEDICAL RECORD of February 28, 1920, under the heading "The Cancer Enigma," we find the following, after discussing various so-called causes of cancer he says, in derogation: "Among other theories advanced may be mentioned eating salt bacon, and the employment of salt as a condiment, acting as predisposing causes of the disease." This statement leads the writer to believe that the Doctor frankly doubts the possibility of salt being the cause of cancer. Further on in his article he says, "Now all these, from my point of view, untenable theories have been advanced and circulated since that pioneer of the science of pathology and master of his subject, Sir James Paget, stated, "The condition of the blood is the predisposing cause of cancer," and I have no hesitation in affirming that his opinion still is accepted as final by all who have given prolonged study to the subject. The question therefore arises: What is the fons et origo of this pernicious condition of the blood stream which converts it into a predisposing cause of cancer?" My answer to the Doctor is, *the presence of an excess of salt*, the correctness of which he is at liberty to disprove.

Dr. Bell's treatment for cancer is very varied. His armamentarium is extensive. It is gunshot in character and embraces many things in its field of action. For example, the Doctor says that hot air gives good results and so does thyroid extract. This extract "has proved in my experience to be in many instances almost a specific when combined with a regulated diet." It seems that the Doctor is not content with one specific but aids its action and states, "gratifying results have been consequent upon the subcutaneous injunction of 2 c.c of magnesium colloid." Again, "good results are also obtained from cold drawn expressed juice of various plants and algae." Further, "another valuable source of this preparation is yeast, * * * a patient having lost thirty-two pounds was put upon fruit and vegetable juices, and egg flip composed of the white of an egg beaten up in a teacup full of fresh milk." At the end of seven months "the patient had regained her former weight." In sarcoma he says, "I have also obtained very satisfactory results from the injection, deeply into the gluteals, of 1 c.c. of atoxyl in iodolysin." The entire article of the Doctor is interspersed with remedial agents, but in no one instance does he give a logical reason for their use in the treatment of cancer, nor tell what a cancer is or on what theory he works to bring about his cures.

The following cases have been treated according to the theory already advanced in the MEDICAL RECORD, September 1, 1917, and with potassium nitrate, supplementing it with mineral salts such as magnesium, calcium, manganese, etc., with the object of replacing the cell loss of these substances.

The writer wishes to lay particular emphasis regarding the correctness of the diagnosis of cancer made in these cases. In every instance the nature of the disease was pronounced cancer by physicians or surgeons who had previously seen the patient. The patient came voluntarily for treatment giving the names of the diagnosticians or was sent by one of them. In no instance did the writer primarily make the diagnosis.

CASE I.—Mrs. H. The diagnosis of the case was given as a scirrhus cancer. No biopsy was made in confirmation as the patient objected to any surgical interference. Because of the absence of a microscopic verification the possibility of doubt creeps in. Indeed, a well known pathologist who saw the case, because he

was unable to view the cells under a microscope, emphatically stated that he did not know the nature of the disease. By all physical appearances the thing does seem to resemble a scirrhus but the writer ventured the opinion that it might be something else. Perhaps an old syphilitic gumma. No? Then a tuberculous lesion. No? Then it must be a brand new disease which is yet to be catalogued. However, four physicians pronounced it a scirrhus and as the majority ruled, treatment was commenced. Examination of the breast revealed an indurated area of inflammation above the gland involving the pectoral muscle. The axillary glands were swollen and sensitive to touch. Both legs were edematous. Obstinate constipation was present and had existed for years. She complained of difficult respiration and was "hungry for air." This is a characteristic symptom of acidosis. There was a dark patch on the cheek, which was redness due to an epithelioma. The tongue was coated and the color of the skin very anemic. In the uranalysis the point of greatest interest in connection with cancer is the high percentage of acidity, 70, and the quantitative examination of chlorides passed which showed 20 per cent. The blood examination showed erythrocytes per cu. mm. 3,840,000; hemoglobin, 60.

Treatment was commenced August 7, 1919, and the patient was discharged cured on March 5, 1920. The erythrocytes are now 4,960,000; hemoglobin 80. There is no edema of the legs, constipation has been cured, and she states her health is as good as it ever was. She is seventy-two years of age.

CASE II.—Mrs. F. Age sixty-five years. Cancer of left breast. Diagnosed by two physicians. Operation refused. Examination shows an ulcerated mass under the fold of the left breast, oozing and with distinct odor; area of redness about four inches in circumference; sharp lancinating pain in nipple; axillary glands enlarged and painful. Treatment commenced by her physician February 10, 1920. Seen by the writer, third time, March 8, 1920. Healing complete, redness absent but a nodule of indurated tissue is felt at the seat of the cancer. This is fibrous tissue and in all probability will remain unabsorbed. Physical condition markedly improved. Still under treatment.

CASE III.—Mr. S. Age seventy-five years. Cancer of jaw. Operated on eighteen months ago. Recurrence. Examination: Half of left jaw absent, ulceration at end of bone, tongue sore, deglutition painful. Treatment commenced January 24, 1920. Ulceration now healing; swelling of tongue and cheek absent. Physical condition good. Prognosis favorable. Four months ago, the patient states, he was refused treatment at one of the hospitals, his condition being then considered hopeless.

CASE IV.—Mrs. S. Age forty-three years. Cancer of neck of uterus. Severe hemorrhage with fetid discharge. Marked cachexia, constipation, and marked debility. Treatment commenced November 12, 1919. Still under treatment March 29, 1920. No hemorrhage and discharge serous and free from odor. Does her own housework, anemia greatly improved, constipation relieved. Gain in weight of nine pounds. Prognosis good.

CASE V.—Mrs. McL. Registered nurse. Age forty years. Abdominal tumor, probably fibrous; has existed for fifteen years. Circumferential measurement thirty-eight inches. Treatment commenced September 2, 1919. In six weeks tumor was so reduced as to show a circumferential measurement of thirty-four inches, which size is maintained and will prove permanent. Treatment continued for four months in all. Patient discharged. Health good. Further treatment not advised.

CASE VI.—Mrs. P. Mother of physician. Age seventy years. Epithelioma on side of nose treated by her son and reported by him to the writer as cured. This patient, the doctor stated, had been treated with radium and the *x*-ray. The disease seemed cured for a few weeks but persisted in returning. A year has passed since treatment with no return of the malignancy.

CASE VII.—Captain G. Police department. Operated on for tumor of the tongue. Recurrence in eighteen months. Radium had been applied to lesion. When seen by the writer the attending physicians had retired from the case giving the prognosis of death within two weeks. Patient was taking ninety grains of aspirin and ten grains of morphine daily. A tumor mass occupied the entire right side of the cheek and neck from the temple and extending below the clavicle. The right cheek and eyelids were edematous, the latter closed by the effusion. Both legs were swollen. The patient suffered most excruciating pain and was forced to maintain a cramped sitting posture day and night. A description in full of this case is much too lengthy for this paper. Briefly then the same treatment was given him that other cases received and was commenced on October 17, 1919. In forty-eight hours the edema had disappeared from the face and legs. The relief in pain and discomfort was remarkable. Within four weeks the cancer mass became reduced to one-half its size and the patient was able to walk, lie down, and sit erect. After ten days narcotics were no longer needed. This patient had lost during his illness one hundred forty pounds, about half his weight. He lived six weeks and died free from pain and peacefully. He might have lived but was unable to assimilate the nourishment given, although fed every hour with highly nutritive substances. The metamorphosis in the cancer tissue from intense malignancy to practically a benign fibrosis was observed by two well-known physicians, one a pathologist, and also by the patient's son, a dentist, who was with him during his last six weeks of illness. That he died from malnutrition and not from cancer was the consensus of opinion of all who had been connected with the case.

CASE VIII. — Mrs. O'R. Tumor left vocal cord. Marked aphonia. Edema of both legs, constipation. Difficult respiration. General anemia. Under treatment these symptoms disappeared and she was discharged in three months, her voice restored but with a slight trace of huskiness. Further treatment was not advised.

Those who have investigated the prevalence of cancer in various parts of the world find certain peoples not afflicted with it and in many instances the disease is unknown. Particularly is this observed by Williams. Quoting from his work, "Natural History of Cancer:" "During a recent extended trip through the Far East I was unable to see or even hear of any cancer, although I met a large number of medical men and made inquiries regarding the same and visited hospitals with a total of many thousands of patients in Japan, China, Korea, the Philippines, India, Siam and Egypt, I met the same response that cancer was rarely seen among those vegetarian peoples."

It might be considered a coincidence that these vegetarians live in some of the countries in which potassium nitrate is found. This salt exists in different parts of Europe and in South Africa, Egypt, India, etc. Probably the saline efflorescence in the soil, consisting of potassium nitrate, finds its way into the human economy with the vegetation eaten. Thus in a natural manner any excess of sodium chloride which may be indulged in would be eliminated or kept within physiological proportions, at the same time the basic minerals contained in the vegetable matter would operate to neutralize acidity and remineralize the tissues. Potassium nitrate is a constituent of vegetable tissue. The thought occurs that sodium nitrate should not be substituted for potassium nitrate as a fertilizer. However, as soon as the customs and manners of life and diet of civilization are adopted cancer develops, and this has been particularly observed in negroes before and after the civil war, and also in primitive peoples of India, Africa, Mexico, Brazil, etc., who previously had been free from it.

Furthermore, it appears that animals living in a wild state are also free from cancer, but develop it

as soon as they are brought into captivity, domesticated, and fed the diet of modern civilization. For example, it is not uncommon to find house dogs and cats afflicted with cancer. The mammary glands of the female dog being the site of preference. The writer was fortunate to discover accidently a cat with cancer of the lip which served to verify the presumption that there is in or about civilization something which predisposes to the development of cancer—and this something is common table salt. This cat is four years old and came into the possession of the family when a kitten. Believing in the popular idea that salt is good for animals the cat's food was generously sprinkled with salt for which the cat developed a taste. After three and a half years of this diet the cat became sick and its fur began to fall. It refused to eat and the upper lip became sore and red. Local remedies were applied, but after six months of treatment in which many things had been tried the cat was taken to a veterinarian who pronounced the condition cancer and advised that the animal be killed. With a history of an excess of salt in the diet, the cat presented an excellent opportunity to try the efficacy of potassium nitrate. Therefore, the same treatment was administered as was given to patients with cancer, with the result that the cat is cured and has grown a new coat of fur.

That salt stands convicted of the cause of cancer seems to be based upon more than circumstantial evidence, for in all the cases of cancer giving a history of an excess of salt in the diet its elimination by potassium nitrate has been productive of cure or in greatly ameliorating the condition and relieving pain. This last feature is noted in a communication which I have just received from Dr. T. Howard Plank of Chicago, in which he says, "I have read some of your articles on the use of potassium nitrate in the treatment of cancer and acting on your suggestion have been able to dispense with the use of morphine." From this it may be assumed that the nerve tissue is being irritated by some chemical substance, the removal of which relieves the patient of pain. Is it not logical to infer that salt is the cause of the pain?

The writer has so far treated cancer of the following histological structures:—bone, glands, liver, stomach, mucous membrane, and skin. In not one case has the condition failed to respond to the influence of potassium nitrate. Some have been cured, others are under treatment and improving, the prognosis pointing to a favorable recovery.

It may well be asked, how long will a patient remain cured of cancer? This may be answered by another question, how long will a person cured of alcoholism remain sober? Therefore, if the causes which operated to produce cancer in the first instance are renewed the disease should recur. A cancer patient knowing that the disease is caused by the excessive use of salt should refrain from its too liberal use. In fact, it is the duty of the physician to instruct the patient regarding prophylaxis. If there is a possibility of recurrence of the disease the patient should make regular visits to the physician so that he may be able to recognize any latent symptoms and give timely warning. We read a great deal about educating the public regarding cancer, but it seems difficult to do so intelligently when all that is now advised is a surgical operation. Hygiene and diet, the very moderate use of salt and plentiful amounts of fresh vegetable substances, containing the mineral salts of which protoplasm is composed, seem to the writer to be the synopsis of public education.

452 Fifth Avenue.

AN EVALUATION OF MINOR SURGERY*.

By MARTIN W. WARE, M.D.,

NEW YORK.

THE fact that you have seen fit to make the order of the afternoon's program "Minor Surgery" is significant that you consider the "minor" to be of "major" import, and I shall furthermore endeavor to justify the saying "multum in parvo" as aptly characterizing minor surgery. For major surgery it is our boast that giant strides have been made; but it must be conceded that whereas a uniformity exists the world over by the pursuit of asepsis, antisepsis, and anesthesia in the practice of major surgery, there is far from anything of a like uniformity or unanimity as to treatment of minor surgical conditions. Of this deplorable state of affairs you may readily convince yourselves by visiting various dispensaries and out-patient departments of any community, and witness the variegated treatment accorded, and again witness the like treatment which physicians in private practice mete out in the stress of first aid, under the cloak of minor surgery. Minor surgery is largely synonymous with "first aid."

During our participation in the Great War, a questionnaire was issued by the Surgeon General to many surgeons and many physicians, to elicit from their replies what was the consensus of treatment in conditions calling for "first aid." Upon this concerted response was predicated the standard instructions of first aid incumbent on the medical corps. Manuals of Minor Surgery extant are antiquated and it is therefore earnestly to be wished for that efficiency in the teachings thereof should now prevail. The standardization, or rather efficiency, of minor surgery is of as much concern as standardization of hospitals; for minor surgery is the major part of the surgical practice indulged in by the practicing physician in the privacy of home or office, encompassing a clientéle larger in its census than that of hospitals or dispensaries. No little wonder therefore that minor surgery, being the bread and butter of our existence should merit revision tending to increased efficiency.

Passing over these admonitions and censurers, I will essay with your indulgence to give some constructive and practical aspects of the commonplace which have engaged considerable of my time these past two decades.

First as to control of hemorrhage.—It is an opprobrium to the medical profession that dilettante parlor surgery instruction still appears in first aid and minor surgery manuals. Thus one still encounters the reprehensible directions "that when confronted with a hemorrhage, pressure manually, preferably with torniquet, should be applied, cen-

*Read before the meeting of the Sullivan County Medical Society, Liberty, N. Y., May 12, 1920.

tral or distal, according to the type of bleeding, whether arterial or venous. This is not only *not* minor surgery but it is also *minus* surgery, since it is at variance with good surgical practice; for the surgeon at the operating table is wont to make pressure directly at the bleeding point and with the finger first, or a sponge in hand, and thereafter may follow forcipressure and ligature or gauze may be left in situ. Anyhow wherever the need of a tourniquet does arise, the surgeon always places it centrally.

Many a hemorrhage from a small sized vein will require nothing further than a direct pressure. To illustrate, I would recall the examination question by an astute surgeon which all applicants failed to answer. The question was put as follows:

"One of two physicians, in full evening dress, returning from a dance was suddenly stabbed in the neck, following which a huge gush of blood took place. What would *you* have done for your injured companion?

Answers: One—would have rung for an ambulance. 'Before the ambulance responded an undertaker would have been more in place'. said the examiner.

Another—to outdistance the previous applicant—offered the use of his pocket instruments, to which the examiner retorted, 'they are not usually carried about at a dance'.

The last applicant thought he would be equal to the occasion, by crowding a handkerchief into the wound. 'That', said the examiner, 'let us assume, was left as a souvenir with the lady."

It therefore remained for the examining surgeon to point out what is done in daily practice—'Place the finger into the wound and holler for help'.

This hypothetical question propounded actually took place recently: Dr X. was out riding with his wife in an automobile when a collision took place, shattering the glass wind shield, a fragment of which struck the wife in the neck and cut her jugular vein. The physician, as reported by the papers, pressed his finger into the neck wound and sped on to the nearest hospital where surgical measures were successfully applied.

Very much in common with this type of hemorrhage is that of varicose veins. Hemorrhage from these needs only pressure with gauze.

In hemorrhage following extraction of the teeth by the dentist, the doctor's advice is often sought—'What to do'? Pressure! Simply take a small handkerchief, roll it and bite upon it, and caution not to look at it for at least half an hour.

At this juncture, I want most emphatically to condemn the Rip Van Winkle practice of the lingering use of styptics. Whilst I do not wish to repudiate the use of modern hemostatics, I for one do not even believe in adrenalin as a hemostatic. When you stop to consider, you will recall that with every application of adrenalin, there is conjoined pressure either of the cotton applicator or pledget of gauze. There are, however, parts where prolonged pressure is of no avail or even injurious. I cite an experience where the flow of blood from a divided vessel of the scalp was staunched by pressure with gauze, deplorably resulting in a large decubitus ulcer, for the skin was exsanguinated by undue pressure against the unyielding bone.

Without available artery forceps, hemorrhage can be readily controlled by simply passing a suture deep enough to encircle the vessel. For the scalp—mere suture of wound will suffice; for the wounds of the lip and tongue, and in rare instances where a nevus is wounded, a well placed suture is the only method.

My advice was recently sought by a physician for the control of a vesical hemorrhage for a prostatic patient declining operation, who bled profusely following each catheterization for retention of urine. I counselled him to leave a large catheter in place and put a 3 lb. bag weighted with sand, shot, or salt over the suprapubic region and never to be forgotten in any hemorrhage—to insure absolute rest, to give the patient an opiate.

It is opportune to dwell on the miscarriage of surgery because physicians, even in the pursuit of minor surgery, do not sufficiently avail themselves of the beneficient use of a general anesthetic. There are a host of conditions requiring such. Innumerable times, I have encountered this shortcoming. Where no general anesthetic is used a focus of suppuration is nine times out of ten inadequately incised. Don't attempt to remove foreign bodies from the nose, or puncture the ear, or reduce a fracture, or attempt to ligate a deep vessel, or do much suturing without a general anesthetic. Contrast what the dentist has gained by his high universal use of N_2O anesthesia in extraction, and analgesia in the operation on teeth. I venture to anticipate a reply that the general physician is at a disadvantage because he has no such facility for giving a transient efficient anesthesia with N_2O.

Nearly 20 years ago, I realized the dilemma of the general practising physician and I turned to use ethyl chloride for the aforesaid purposes. I was the pioneer in its use for general anesthesia in this country. Its safety having been vouched for, I claim for it a superiority over nitrous oxide, because it is more readily obtainable in drug stores, it requires no special apparatus, and is most portable. Just this parting reminder to inspire confidence in its use in minor work. Pure ethyl chloride is adjudged absolutely safe for inducing anesthesia and such being the case, I plead for its wider acceptance. Use it as you do any other anesthetic. Rules for any of the anesthetics apply equally in its administration.

The ritual exacted in the toilet of wounds, made in the performance of an operation applies with equal force to all accidental wounds. I take it that nowadays a pair of sterilized gloves are part of every physician's kit. Any gross dirt should first be removed with benzine or ether, and tincture of iodine should be applied without the preliminary use of water or soap. The pitfalls of accidental wounds are the control of hemorrhage, tetanus, and foreign bodies. Hemorrhage, as aforesaid, being stayed by pressure with gauze, not cotton, a cautious survey of the wound should be made to learn whether a joint is laid open; and in transverse and punctured wounds of the forearm and hand, if a tendon is divided. It is all too frequently an error of omission to suture wounds of hand and wrist and gloss over the injury of the tendons, so easily diagnosticated by noting the abeyance of function by eliciting motions of extensions and flexion. To attempt a primary suture of tendon with local anesthesia, I regard as an error of commission. This conviction is gained from experience, for retraction of the divided tendon ends may demand prolonged manipulation for which general anesthesia is bet-

ter; and as accidental wounds are prima facie infected wounds, local anesthetics injected are risky in their tendency to spread the infection. Gross foreign bodies readily presenting should be removed and if it is a fragment of wood, the overlying parts should be split under local anesthesia to guard against a particle being broken off and left behind. The enlarging of the wound in the case of penetrating wounds and those of pistol shot variety secures additional advantage in that air gains access to the cellular spaces and thus combats the development of the anaerobic tetanus bacillus.

Best surgical judgment commends the immediate injection of large quantities of tetanus antitoxin in all wounds contracted along the highways and in field work. I think the epidemic of tetanus about 10 years ago, incident to 4th of July celebration was due to the filth of streets (host of the tetanus bacillus) infecting the hands. I recall my good fortune to have had no tetanus in the dozens of cases treated at the time which I attributed to the freedom of exposure of all the wounds under general anesthesia, excision of all the lacerated tissues, and use of 5 per cent. solution of carbolic acid along the lines recommended by Baccelli.

The recognition of foreign bodies, such as particles of glass of the lead variety or needles, it is true, is vastly facilitated by the *x*-rays. Their presence once established, their removal is facilitated by use of a rubber constrictor to render the field bloodless. Needles are most elusive foreign bodies—even located by *x*-ray, they are very difficult to remove. I daresay many of you have been chagrined or witnessed such on the part of the surgeon trying to ferret out the needle. The wanderings of needles are famous in the annals of medical literature and the impunity of their itinerary is likewise. I always plead "non vult" against their removal, even where there is a metastatic deposit of that needle in the brain of the host. If then, I am none the less importuned to search the haystack, I make a clean breast of the difficulties and once more plead "non possumus" before yielding to force majeure.

The various pitfalls of accidental wounds guarded against, the question of suture is paramount. It may be necessary, if the wound is very grimy, to give an anesthetic to effect cleansing. As for suture, I favor rather little than too much. Not uncommonly, I have seen a half dozen stitches applied to a wound little larger than one inch. In wounds about the face, I presume to advise abstaining from the use of sutures or reduce them to a minimum; since the puncture of the needle may emphasize the scar by the formation of cheloids.

Of late years, I have satisfactorily employed sterile strips of zinc oxide where there is no great tension. Whether stitches or plaster, an interval of half an inch should be allowed between each. Such wide spacing allows for the escape of secretions. The zinc oxide plaster strips may be sterilized by passing the sticky surface over a flame and cooling before bringing in contact with the skin. It is very rarely, notwithstading effective iodine sterilization, that you can sew up a wound without some provision for drainage, be that drainage through a wide interval of sutures or by placing a small piece of rubber tubing, or a piece of gutta percha tissue quickly sterilized by immersion in tincture of iodine.

Wounds of very recent date made with sharp instruments on a comparatively clean surface can be dressed with aseptic dry gauze—no iodoform gauze is necessary. Drainage with gauze is bad practice, the free gauze end dries out and the gauze acts like a cork so that the secretion is pent up.

The factor of rest by confinement to bed, which is essentially elementary in the after treatment of major surgery, is through perversity quite uniformly wholly omitted in minor surgery. A generous sized well-cushioned splint and suspension of the arm or forearm in a sling should invariably supplement any treatment of whatsoever wound injury or infection, and healing will be greatly facilitated and hastened, and much pain allayed. In this connection, I would counsel from the start, the application of splints of sufficient length to immobilize the painful joints of rheumatism and gonorrhea. This practice is altogether too frequently overlooked. You will recall that the strictest orders prevailed in all the Allied armies, to apply a splint fortwith to all injured members. Violation of this order called forth severe censure.

Passing on to fractures, I can deal with them only in a fragmentary way. The universality of *x*-rays has usurped the development of clinical acumen and with the bedside unit soon to be the vogue, clinical diagnosis of fracture will receive still further setbacks. But notwithstanding, there remain numerous exigencies that call for the art and skill of the family doctor as of old, to recognize a fracture. Fracture of the hip in the aged, I would single out to best exemplify this. With the prevalence of *x*-rays, sprain is fast disappearing from the vernacular and the lesson has to be learnt that local bone tenderness with or without extensive discoloration from extravasted blood, incident to indirect violence is strongly presumptive of fractures.

In general, I am for the earliest and immediate application of plaster of Paris bandage as the best and quickest way to reduce the swelling, allay the pain, and hold the fragments in place. The reason that the use of the plaster of Paris bandage is so much deplored is traceable to the atrocious commercial product on sale. An expert must needs likewise fail if he would use the plaster of Paris of Commerce. Herewith a hint to overcome the shortcoming. Unroll the boughten bandage reroll it very loosely and remove the large excess of plaster. Then if you will pad the conspicuous points with cotton and exert neither traction nor pressure in applying the bandage, you will experience no ill effects of interference with circulation, nor cause pressure sores or pressure paralysis. The use of ice-bags to remove swelling is a waste of time. More efficient is great elevation of the limb and elastic pressure of a flannel or elastic woven or gum elastic bandage. It should be recalled that a number of hours lapse before the necessaries can be assembled for use of plaster and preparation for anesthesia effected, and in that interval the swelling, even untreated, has attained its maximum, and if treated as outlined it will be limited. At any rate, I offer you the assurance of a committee of the American Surgical Association, whose investi-

gation on the treatment of fractures endorses the earliest possible use of the plaster of Paris bandage in fractures of the extremities.

It would be a matter of supererogation to tell any representative body of physicians that every infection should be incised. But may I reiterate that a general anesthetic is a *sine qua non* for the proper execution of the incision. All too frequently a fatal sepsis ensues because the patient demurs to a second operation when the first was done without an anesthetic.

The paradox of infections is certainly a furuncle, commonly designated a boil, and facetiously referred to as an ingrown hair, which I have never seen. A furuncle is potential of much suffering and evil, and notwithstanding that osteomyelitis and septic infarct of the kidney are not infrequently traceable to it, yet empiricism has the upper hand in its treatment. In the initial stage, I prefer the use of flaxseed poultices or a poultice of the clay ointments, and when liquefaction has set in, spontaneous perforation may result or a small incision will facilitate expulsion of the core. At any time that adjacent glands become tender or enlarged, general anesthesia and incision are in place.

The dressing of suppurating wounds of small dimensions is best effected by the use of wet dressings, held in place by a gauze bandage. Covering the wet dressing with impervious oil silk or guttapercha tissue favors bacterial decomposition. Such practice is at cross purposes with principles of all dressings, the aims of which is to absorb the discharges and then by virtue of evaporation or the contained antiseptics, to render them more or less innocuous.

Deep-seated abscesses, not involving the overlying, cellular tissues and skins, such as gland abscess, may be drained through a small opening at a dependent point with a rubber drain tube. The cure of a cold abscess, however, is well within the province of minor surgery. It may not be amiss to dwell on the technique insuring its successful outcome. I wish to emphasize that puncture should be by a circuitous route through healthy tissue, and not directly over the abscess. Contents evacuated, the cavity is to be washed clean till fluid returns clear and then a glycerine emulsion of 10 per cent. iodoform and 1 per cent. gauiacol is to be injected through the same cannula that was used for evacuating. This procedure is to be repeated with diminishing quantity of the emulsion until the cure sets in.

I do not dwell on the Carrel treatment, which is no concern of minor surgery; the Carrel treatment disregards the rule of making the incision at the dependent point. It is fundamental with Carrel to sterilize in loco, wherefore the Dakin fluid must be allowed to pool and the escape of pus is from the top of the cavity.

"Débridement" of war surgery—the removal of all diseased tissue—has a limited application in minor surgery. The excision of a carbuncle well into the healthy area antedates "débridement" and bears some resemblance to its principle.

Wet dressings should be of liquor Burowii (alum acetate), boric acid, Thiersch solution, NaCl. 0.9 per cent., and dilute alcohol, and where pain is severe, carbolic acid 1 per cent. at the most because it acts as an anesthetic, but only for a limited time in order to guard against the tendency to gangrene.

Burns being a species of injury the aforesaid treatment obtains, with additional factors to be contended, namely—the extent of skin destruction baring large areas of sensory nerves and the variable period of reconstruction of the skin. Dependent on each phase, a burn would call for different treatment. A saline wet dressing at the start or continued immersion in a saline water bath to combat and reduce infection, later to be followed by bland ointment, and where the secretion is scant, some desiccating powder. Exposure to air and light allowing a burn to heal under a scab is by no means unsurgical.

The open air treatment and exposure to sun of granulating surfaces is a valuable resource. At night contact of clothes and bedding is obviated by suspension and the use of a cradle.

In contrast to the wounds with large extent of destroyed skin is a "sinus" or "seton-wound." Providing no foreign body, diseased bone, or specific infection, such as tuberculosis or lues, is underlying, the healing may be quickly brought about by sterilizing the tract with carbolic acid or iodine, and when microscopic examination discloses organisms reduced to a minimum, a Beck's bismuth paste, sterilized and injected, will very often pull off the trick.

The treatment of ulcers of the simple variety is covered in the remarks of granulating wounds, and such directions will carry you far, if, in the case of a leg ulcer, the victim would but give the leg just that amount of rest which is wont to be ordinarily advised in a like ulcer on the upper extremity.

In conclusion, I submit that minor surgery be dignified as major surgery, applied to surgical ailments, minor in kind not in degree, and with that due sense of proportion which physician and surgeon alike should exercise, there is but one surgical effort for capital or minor ailments.

27 East Eighty-first Street.

ECZEMA OF THE VERMILION BORDER OF THE LIPS.

By DOUGLASS W. MONTGOMERY, M.D.,
AND
GEORGE D. CULVER, M.D.,
SAN FRANCISCO.

A DIFFICULTY arises at the very beginning of this subject, as we are not sure that we ever have seen a case of true, patchy, vesicular eczema of the lips. Our material consists of either exfoliative cheilitis without vesiculation, or cases which appear to be analogous to blepharitis marginalis, and which are associated with seborrhoic eczema, or still other cases which are analogous to keratotic patches on the free surface.

Catarrhal Inflammation of the Red of the Upper Lip.—The lower lip is much more subject to trouble than the upper one. There are, however, cases of obstinate catarrhal inflammation of the red of the upper lip with acute exacerbations, and accompanied by anteroposterior cracking, and as a consequence,

streptococcic infection with swelling and deformity of the whole lip. In two of these cases seen by us, both in young females, there was also eczema of the navel, and one of them had a patchy psoriasis. These cases, leading to enlargement of the upper lip, were at one time included in the large, inchoate group of scrofula, and indeed, were often associated with catarrh and tuberculosis of the respiratory tract, and tuberculous enlargement of the cervical lymphatic nodules. Treatment is often not brilliantly successful, because of the difficulty of controlling the gastrointestinal and nervous troubles, of which they are one of the expressions. Everything of a general nature, both dietetically and hygienically, must be done to improve the general health.

During the acute exacerbations, weak subacetate of lead lotions or bathing with a saturated solution of boric acid to which 10 per cent of liquor alumini acetici may be added, are ameliorating. One of the best salves is boric acid ointment with the addition of one or two per cent of camphor. The one per cent. yellow oxide of mercury ointment, so much employed by oculists, is also excellent.

Eczema of the Lips as it Occurs in Those Having the Exudative Diathesis.—Often young people, especially young girls, have a blazing red prominent lower lip, frequently desquamative, not infrequently herpetic, and often showing a tendency for a deep crack to form anteroposteriorly in the median line. We infer that the crack forms here because it is a fetal suture, and therefore weak. This affection is particularly apt to occur in soft, rotund, young girls, with a fine textured, fair skin and infantile fingers, who have the exudative diathesis. It may lead to permanent scurfiness of the edge of the lower lip, with permanent enlargement of the whole lip.

The constitutional treatment, involving attention to exercise and diet, is of great importance, but as the disease occurs in particularly effeminate people, this is difficult of attainment.

The local treatment is the same as for the previously mentioned class of cases. When the cracking is deep and stubborn, a much heavier salve must be employed—one made from lead plaster 60 per cent., vaseline 38 per cent., and 2 per cent of salicylic acid. This ointment is spread on stout cotton cloth and adapted to the lip at night. During the day it is to be frequently smeared on the lip so as to form a protective coating. As advised by Pusey, an adhesive plaster brace may be applied across the lip to prevent it stretching in the movements of the mouth. A weak nitrate of silver solution may be painted in the crack. It is best to do this very thoroughly and then not to repeat it for several days. In cases in which the crack has existed for a long time, is very deep and surrounded by considerable inflammatory infiltration, radium heavily screened and retained for some hours may succeed in effecting a cure when everything else fails.

The Scurfy, Scaly Lip of the Outdoor Worker.—There is another most important group of cases consisting of men in outdoor occupations, exposed to wind and weather. This type is not infrequent among the teamsters and auto drivers of the hot interior plains of California. The lips become dry, scurfy, often unduly full, and tend to crack. Often the exposed red assumes the appearance of scurfy, roughened skin. Often, also, these men have that fair type of skin which burns but does not tan in the sun. Gastrointestinal disturbances undoubtedly aggravate this condition. The lip tends to crack, and especially so, if the man smokes, and in such a crack an epithelioma may develop.

The treatment is the same as for the preceding group of cases. The heavy lead plaster ointment is particularly valuable.

The cracks in these cases must be taken seriously, and if they do not heal under simple means, and especially if they show induration, they should be proceeded against as if potentially cancerous. They may be curetted, and burnt either with trichloracetic acid, or with the acid nitrate of mercury. And if proceeded against in this way, it should be with the intention of thorough eradication, and of subsequent treatment of the wound as a simple wound, using the mildest dressing and avoiding further cauterization.

Far superior to this procedure, however, is the treatment by radium, employed in the same way as for cancer.

Patches of Hyperkeratosis.—A scaly, rough patch may develop on the external, or visible, aspect of the red of the lower lip, that is to say, on that part of the mucous membrane of the lip which closely resembles the cutaneous surface. These patches are in all respects similar to seborrhoic keratoses, so frequently seen on the face and on the back of the hands, and are frequently associated with them on the same patient. As before mentioned, the patch may be scurfy and roughened, in which case the hard, rocky masses may cling tenaciously to the mucous membrane. On the other hand, the patch may shed, at intervals, a fine, translucent pellicle. After a variable time—it may be months or years—the base becomes indurated, and the other clinical characteristics of epithelioma develop with varying degrees of speed.

There is still another group of these dry, scaly, precancerous affections which, for lack of a better classification, may be included in the eczemas. A dry, scaly line forms from side to side across the lip, situated about midway between the cutaneous border and the summit. It may stretch from one corner of the mouth clear across to the other, or it may be broken. It may be a roughened, brown line of dry epithelium, or it may be a narrow, brown, facetted line. We believe this line to be the same one seen in the "rosebud mouth" of the infant, and to represent the junction, in the fetus, of the mucous membrane resembling the cutaneous surface with the mucous membrance resembling that of the oral cavity. It is in this line, when roughened, that an epithelioma is apt to develop, and the recognition of this line is of importance because the epithelial degeneration, of which the epithelioma represents the maximum degree, extends out along it for a very considerable distance on each side of the epithelioma proper. Therefore, any operation failing to take this into consideration is liable to be a failure as not being inclusive enough.

It is our experience that surgeons habitually neglect this line, as they are intent only on eliminating the epitheliomatous nodule itself, or in ex-

tirpating the lymphatic channels along which the epitheliomatous cells may float.

The treatment of these keratoses of the exposed red of the lower lip is identical with that of the keratoses of the skin. The base should be cleared either with the curet alone or by first softening the hard masses with liquor potassæ and then curetting. After curetting, the base may be cauterized with pure trichloracetic acid, followed by water or boric acid solution to prevent overaction. After this, boric acid ointment should be used until healing is complete.

It is in these cases also that *x*-rays and radium are so beneficial, especially the latter. The employment of radium well screened secures the best results of any we have obtained. In many so treated it is impossible to tell that any previous lesion had existed.

The illustration indicates what would be regarded as an inadequate operative procedure. The patient, a woman thirty-seven years of age, for years had been afflicted with psoriasis. Her skin, as can be seen in the photograph, was far too atonic for her years. It sagged at the jowls, under the chin, and

Eczema of the vermilion border of the lower lip.

in front of the neck, as can be seen in the photograph. She had a number of sebaceous glands in the mucous membrane of the upper lip, the significance of which as pertinent to the lesion for which she consulted us was not evident. She presented herself, January 6, 1920, with a rough, irregular, rocky, hard, adherent keratosis of the exposed red of the lower lip which had existed for several months. It was tightly adherent, and had an anteroposterior crack through its center extending down into the "quick." From each side of this central keratosis there extended a linear keratosis. This lay in the usual situation, midway between the lower border of the red of the lower lip and its summit. It did not extend on either side as far as the corner of the mouth. The lesion was undoubtedly a seborrheic keratosis, and not a patch of psoriasis, and it was a lesion which, if left to itself, would likely have degenerated into an epithelioma.

The keratosis was removed with liquor potassæ and the denuded base was found to be bright red and without any induration whatever.

She was treated with radium, a 12.50 mgm. plaque screened with 0.4 of lead and twelve thicknesses of writing paper, held in place for five hours. Under boric acid ointment, perfect healing took place, both of the central keratosis and of the lateral wings.

The point wished to be brought out is that if the central keratosis had been removed by a wedge-shaped excision, as indicated in the illustration, a cure would not have resulted, as the lateral wings would have been left to develop the same kind of lesion, and besides, the patient would have had a disfiguring scar.

323 Geary Street.

INTESTINAL PARASITES AS A CAUSE OF APPENDICITIS: REPORT OF A CASE

By WALTER W. CRESS, M.D.,

Mare Island, Cal.

Lieutenant Commander, Medical Corps, United States Navy.

In the early literature on appendicitis, a great deal of attention was directed to the relation existing between intestinal parasites and that disease. Kelley, in his book, "The Vermiform Appendix and Its Diseases," devotes considerable space discussing the probable relation that enterozoa bear to diseases of the appendix, and cites many case reports in which intestinal parasites have been mentioned as an etiological factor.

Among the more common parasites that have been found in the appendix or in appendical abscesses at the time of operation, are *Ascaris lumbricoides, Oxyuris, Echinococcus, and Trichocephalus dispar.* Oxyuris has been frequently found in the normal appendix as well as in diseased appendicies removed at operation, and it would appear that many surgeons are of the opinion that the parasites are capable of provoking the attack.

It is conceded by all that intestinal parasites may, in children, give rise to symptoms, which, in their sudden onset and stormy character at least, closely simulate acute appendicitis.

Erdman, in twenty-nine cases of acute appendicitis in children, in four instances found from six to thirty pinworms in the appendix.

Amebiasis is of interest, especially in tropical countries, in connection with diseases of the appendix on account of the frequency with which this disease is diagnosed as appendicitis, as well as the frequent occurrence of perforation of the appendix as a fatal complication of amebic dysentery.

In a series of autopsies on this disease in Manila, the appendix was found to be involved in 7 per cent. of the cases.

Stitt states that in chronic amebic dysentery there is usually a moderate leucocytosis and this with the pain and tenderness about the cecum, may lead one to diagnose appendicitis and operate on a normal appendix. Rogers, who had a wide experience with amebic dysentery in India, observed that the appendix is frequently affected and that perforation is not uncommon.

After a careful review of the available literature, I have been unable to find any reference to a case in which *Lamblia intestinalis* was considered to have been the cause of pathology in the appendix or in which a case infected with this parasite was diagnosed as appendicitis. In fact the literature

would lead one to believe that infection from the *Lamblia intestinalis* is infrequent in this country.

CASE.—G. T., age nineteen, white male, a native of North Dakota, was admitted to the surgical service with a diagnosis of acute appendicitis. The family history was negative.

Previous History: Influenza one year ago. Diarrhea, accompanied by pain in abdomen, six months ago. Denies venereal diseases.

Present Complaint: About six hours before admission to hospital patient began to have colicky pains in the lower abdomen. The pain at first was diffuse, but later became more severe in the right lower quadrant of the abdomen. He was nauseated, but did not vomit. No cough. Bowels always constipated.

Physical Examination: Well developed young male. Head and chest were negative. Abdomen was slightly distended. There was some tenderness on deep pressure over the right lower quadrant, with rigidity over the right side. Temperature on admission was 98°, pulse 76. White blood count, 10,400; polymorphonuclears, 78 per cent. Urine was negative. On the following morning the temperature was 99.8°, pulse 86. The pain, tenderness, and rigidity were more marked than on admission. The patient was seen by the members of the surgical staff, one of whom urged immediate operation.

Operation: Right rectus incision. On opening the peritoneum a small amount of serous fluid escaped. The intestines were distended with gas and were packed off with difficulty. The ileum, the cecum, and that portion of the colon in sight were edematous and markedly congested. The appendix was swollen, tense, and hyperemic. The appendix was removed, the stump was inverted by means of a pursestring suture, and the abdomen was closed without drainage. Some difficulty was experienced in closing the abdomen on account of the distention of the intestines.

Convalescence was uneventful until eighteen hours after the operation, when the temperature suddenly rose to 103° and pulse to 114. Mild delirium, with clouding of consciousness, set in and during the next twenty-four hours there were eighteen bowel movements, diarrheal in character. The stools consisted chiefly of blood and mucus, and had an offensive odor. The face was flushed and the tongue was covered with a dirty gray coat. The patient complained frequently of pain in the abdomen. On the third night, while delirious, he got out of bed and walked to the bathroom.

Blood Count: 13,700, white cells. Twenty-four and forty-eight hour blood cultures were negative. A thorough examination of the stools by cultural methods failed to reveal the presence of any pathological organism; however, on microscopical examination there were found, in large numbers, certain actively motile, flagellated, pear-shaped organisms, identified as *Lamblia intestinalis*.

The temperature remained at 101° to 103° and the bowels continued to move at frequent intervals until the fourth day, when all symptoms subsided. With the drop in temperature and pulse rate the diarrhea ceased, the patient became more alert and asked for food, and convalescence from this on was uneventful.

The patient was born in North Dakota and had never been out of that State until one week prior to the onset of the present illness. He had always lived in a Norwegian settlement and during the past year a number of immigrants from Norway had settled in his neighborhood. It is interesting to note that many of the cases of dysentery supposed to have been caused by the *Lamblia* have been reported from countries bordering on Norway.

As to what influence this parasite had in causing the pathology in the appendix and in the subsequent diarrhea, I am unable to say. Grossly, there was sufficient pathology in the appendix to account for the symptoms present before the operation. Unfortunately, the appendix was not submitted to the pathologist for miscroscopical examination.

The *Lamblia intestinalis* was first observed and described by Lamblia of Russia in 1859. Later the parasite was found in dysenteric stools in Italy, Germany, Finland, and other European countries. Cases were reported in this country by Stiles who succeeded in inducing the infection in guinea pigs by means of cysts of *Lamblia* obtained from human feces. Stiles is of the opinion that flies may transmit the infection.

As to the treatment of this condition, no one drug seems to be successful in all cases. Methylene blue is recommended but the dose to be sufficient must be large and may cause symptoms of poisoning. Emetine has been used, but the results have been rather indifferent. In the case cited, there was no treatment directed to the destruction of the parasites.

Examination of the patient's stools before his discharge from the hospital, failed to reveal the presence of the parasite.

NAVAL HOSPITAL, MARE ISLAND, CAL.

PROSTATIC BACKACHE.*

BY A. GOTTLIEB, M.D.,
SAN FRANCISCO, CAL.

IN the course of chronic prostatitis low backache is a frequently complained of symptom. The patient attributes it, as a rule, to "kidney trouble" and consults the urologist, although the pain is located in the sacral, sacrolumbar and sacroiliac regions of the spine, and is aggravated by spinal motion and a lasting upright position.

Some textbooks on Urology mention this symptom only casually. In Keyes Urology[1] we find the statement: "Pain in the back is usually in the upper sacral region, constant aching in character, uninfluenced by urination." Pedersen[2] says: "Spondyloarthritis is not uncommon a complication of gonorrheal disease of the joints and the sacroiliac joints are involved sometimes." Guiteras[3] speaks of a possibility of gonorrheal arthritis of the sacroiliac and intervertebral joints.

From these statements may be concluded that the urologist regards the backache as being due to gonorrheal inflammation of the joints and muscles of the lower spine. This assertion may be supported by Billings[4], Rosenow[5], Adami[6] and others, who have proven beyond question that bacteria may live in confined regions in certain organs for indefinite periods of time and that the prostate and seminal vesicles are important sites of such infections, in view of the frequency with which they are attacked by the gonococci and other micro-organisms and the difficulty of eradicating these sites of infection. The bacteria or toxins may free themselves from these places of hiding, enter the blood stream and lodge in the terminal arteries of the joints or in the capillaries of the muscles and other connective tissues where pathologic lesions are then set up. These lesions in the joints, muscles, fasciæ, and joint capsules have been named by Luff[7] "fibrositis" and have been described by him as consisting of a hyperplasia of the connective tissue with exudation and proliferation of the fibrous tissue elements. This in-

*Read before the San Francisco County Medical Society.

flammatory hyperplasia in the tissues of the small of the back may undergo resolution and entirely disappear if the focus of infection is attacked early and eradicated; or, if treatment is neglected, it may go on to organization and formation of adhesions, thickening, and contracture of the connective tissues. This latter is what causes the stiffness in the spinal area involved.

In the causation of this pain must not be disregarded the static element to which Reynold and Lovett[8] have first drawn attention. They ascribed the pain in the muscles and ligaments of the back to the abnormal attitude of the patient. Lovett[9] has pointed out later that inflamed pelvic organs may induce the patient to assume an attitude in standing or walking which increases muscular backstrain of a static nature. He pointed out only the woman with pelvic disorders, but this statement is true of the man with prostatic inflammation as well. Besides that, many of these patients suffer from flat or at least pronated feet which contribute to the backache. It is necessary, therefore, not to overlook these static disturbances of balance in the diagnosis and treatment of this condition.

The treatment should be constitutional and local to the prostate and the back. Constitutional treatment consists in observing hygienic and dietetic rules applied to every aspect of the individual's life, such as regularity of bowels and temperance in eating and drinking. The treatment of the prostate is left to the skill and knowledge of the urologist.

The most effective treatment of the back is the application of heat followed by ionization, diathermy, vibration and massage, and support to the pelvis and back, as well as correction of any possible foot abnormality.

Local heat causes a state of active congestion, stimulates leucocytosis and tissue metabolism. The heat is applied by means of a high candlepower incandescent lamp, if a limited area of the back is involved, or by means of a hood lined with numerous electric bulbs which is placed over the back from the dorsal region above covering the buttock below. The heat is applied directly to the skin. After the radiant heat exposure for about 20 minutes, the part is red, feels burning hot, is relieved of pain, and the patient enjoys more motion in the spine, because the spasticity of the muscles has relaxed. Following this exposure, ionization with iodine ions is instituted.

Ionization consists in applying a 2 per cent. solution of lithium iodide to the affected region by means of the negative galvanic pole; the positive pole, the indifferent, is placed on the opposite surface. A lint padding of the negative electrode carries the solution of the iodine, while that of the positive is soaked in sodium chloride solution. The strength of the current varies with the tolerance of the patient and ranges between 30 and 50 milliamperes. The time of exposure is gradually and slowly increased from 10 to 20 minutes and treatment is repeated every other day.

Another electric current of value is the D'Arsonval, which I use with great benefit on alternating days with the galvanic ionization. The D'Arsonval current distributes heat in a straight line between the electrodes. One electrode, large enough to cover the lumbar and sacral regions, and the other on the opposite surface, on the abdomen, are placed in contact with the skin. The exposure is about 20 minutes. Either of these procedures is followed by local vibration and massage for the purpose of dissipating the artificially induced effusion and dispersing and absorbing the fibrous tissue thickening.

Besides the constitutional and local treatments, the faulty statics mentioned above, if such exists, must be corrected. The patient is provided with properly fitting shoes with a lift on the inner half of the sole and heel to correct the pronation; he is instructed how to walk, stand, and exercise so as to increase the muscular strength of the legs, and, when indicated, he is supplied with a made-to-order arch support.

A canvas corset or pelvic belt is ordered for the patient with the object in view to rest and support the strained muscles. Such belts, if well fitting, afford very great relief to the small of the back.

THE MENTAL CONFLICT.

By H. LAVESON, M.D.,
NEW YORK.

A MENTAL conflict is a battle between two opposing groups of ideas, part of which are acceptable to the patient and part antagonized by him. These groups of ideas may be either conscious or unconscious. As a rule conflicts are of a moral nature and frequently refer to the grossly sexual character of the patient's thoughts. The attempt to banish these thoughts produces the conflict and the neurosis. Mental dissociation is the result of conflicts. In every mental conflict there are two opposing forces, the positive or the force of reality, by which we come into touch with the external world, and a negative, through which reality is opposed by shutting off the external world. It is this last which produces the shut-in personality or the negativism which is so characteristic of dementia præcox.

Bleuler presents us with a psychological axiom that every tendency is balanced by its opposite tendency. Similarly all other tendencies, under the stress of emotions, are balanced by their opposites —thus giving an ambivalent character to their expression. This theory rests on clinical observation of catatonic negativism, which more than proves the existence of contrasting tendencies and values. These facts are well known to psychoanalysis, where they are summed up under the concept of resistance. But this must not be taken as meaning that every positive psychic action simply call up its opposite. If we investigate psychoanalytically a

case of obvious ambivalency, *i.e.* of a more or less unexpected negative instead of a positive reaction, we find that there is a strict sequence of psychological causes conditioning negative reaction. The tendency of this sequence is to disturb the intention of the contrasting or opposite series, that is to say, it is resistance set up by a complex.

The original method by which the conflict was dealt with therapeutically, and still the most important feature of its therapeutic handling, was to get the unconscious factor into consciousness. So long as the unconscious factor remains unconscious the conflict continues with no power to bring matters to a satisfactory conclusion. The patient, the host of the conflict, is in a position similar to a soldier in the trenches being shot at by a sharpshooter using smokeless powder. He is conscious of the impact of the bullets about him and of his danger, but he does not know what to do about it, he does not know which way to turn, he is as apt to move in the wrong as in the right direction. Just as soon as he can learn the location of the sharpshooter it will be a relatively simple matter to move around a bend in the trench and get out of range, but until he learns this he is helpless. And so the first effort is to help the patient learn this, to help him get the unconscious factor into consciousness.

Those at all familiar with psychoanalysis will know that the opposing forces of the conflict are, in psychological terms, the conscious and the unconscious; that is by what these two terms represent, the unconscious representing the inherent and acquired tendencies, the conscious representing the moment when they come into active touch with reality, in an effort to effect an adjustment. The conflict is at the very root and source of life, it is the very stuff out of which life is made, and the necessary pre-condition of progress. Innumerable examples might be given to show the presence of conflict at the psychological level. Hunger brings about those activities necessary for the procurement of food and the consequent appeasement of the craving. The desire for money prompts those activities which lead to its acquisition and so bring about a state of affairs that leads to satisfaction by supplying the stimuli for generating neutralizing reactions, thus relieving the stress in the system. Fear prompts to run away and get into an environment that will give the feeling of safety. Anger prompts the killing or injury of an enemy.

The essential nature of a conflict is the existence of two opposing forces. Action and reaction are equal and in opposite directions. Motion meets resistance in the opposite direction, the conjunction of two forces striving in opposite directions, one succeeds in dominating the other. The conflict never results in a draw; on the contrary, first one of the opposing forces gains the ascendant, the other is for the time being worsted, then the other is successful, and so this process goes on about a central point, like the needle of a tangent galvanometer, constantly in motion, swinging first to one side and then to the other of the zero mark on the scale, but never coming to rest—a moving equilibrium.

When an emotion is aroused a conflict necessarily occurs between its impulse and that of any other existing affective state, the impulse of which is antagonistic to the aim of the former. Consequently, instincts and sentiments which, through the conative force of their emotion, tend to drive the conduct of the individual in a course in opposition to that of a newly aroused emotion, meet with resistance. Whichever instinct or sentiment, meaning whichever impulse, is the stronger necessarily downs the other; inhibits the central and efferent parts of the process—ideas, emotions and impulses—though the afferent part conveys the stimulus to the central factor. Thus processes of thought to which the inhibited sentiment or instinct would normally give rise, or with which it is systematized, are likewise inhibited and behavior is correspondingly modified. These statements are descriptive only of what is common experience. If one recalls to mind the principal primary instincts such as the sexual, anger, fear, tender feeling, hunger, self-abasement, self-assertion, curiosity, etc., this is seen to be an obvious biological truth. Fear is suppressed by anger, tender feeling, or curiosity, and vice versa; hunger and the sexual instinct by disgust. The sentiment of love for a particular person may be completely suppressed by jealousy and anger. Hatred of a person may expel from consciousness previous sentiments of sympathy, justice, pity, respect, fear, etc. Fear may be suppressed in a human being if impelled by great curiosity over a strange object. Instead of taking to flight he may stand still in wonder. The suppression of the sexual instinct by conflict is one of the most notorious experiences of every-day lift. This instinct cannot be excited during an attack of fear and anger and even during moments of its excitation, if there is an invasion of another strong emotion the sexual instinct at once is repressed.

ON THE USE OF BENZYL BENZOATE IN PERSISTENT HICCOUGHS.

By DAVID I. MACHT, M.D.,

BALTIMORE, MD.

(From the Pharmacological Laboratory of the Johns Hopkins University.)

It is some two and a half years now since the author first announced the discovery of the interesting therapeutic properties of some benzyl esters, and more particularly of benzyl benzoate.[1] The pharmacological data leading up to the discovery and the therapeutic indications for the use of this drug, as well as reports of clinical cases treated with it, have also been published,[2] and shorter résumés on the subject have appeared in the Proceedings of the Association of American Physicians[3] and the *Journal of the American Medical Association*.[4] It may be stated at present that the therapeutic indications for the use of benzyl benzoate, as first predicted by the author, have been completely corroborated by the subsequent experiences in the hands of the author as well as of other physicians; and furthermore, that certain new applications of the drug in therapeutics have been discovered which were not originally thought of by the author. In the present communication the writer desires to call attention to a minor but none the less important therapeutic use of the drug.

The author, as well as a number of other physicians, who have communicated with him, have found benzyl benzoate to be an invaluable medicine in the treatment of persistent hiccoughs of both adults and children. Not only has it been found useful in allaying the ordinary mild forms of hiccough so common in infants, but the drug has been found to be efficient in stopping those forms of hiccoughs may be termed pernicious, that is, those cases in which the phenomenon persisted for long periods of time, lasting from twenty-four hours to several days, and in which the singultus was unaffected by all other forms of medicinal treatment, both external and internal. The author has collected a series of some ten such cases, of which the following three may serve as illustrations.

CASE I.—M. E., age 28, came to the author complaining of persistent hiccoughs which had continued for over 24 hours, without yielding to the ordinary medication in vogue. The patient was given a solution of benzyl benzoate, 20 per cent., and ordered to take 25 drops in water every 4 hours. One dose of the medicine was sufficient to stop the hiccoughs, and apparently cured the patient, as he has had no recurrence since then.

CASE II.—A man of 64 years came under the observation of Dr. B. Sacks of the Hebrew Hospital, Baltimore, suffering from persistent hiccoughs, which started several days previously and which could not be relieved in any way. In the hospital various external applications, such as mustard plasters, were tried without any success. Then medicine was given internally, but neither bromides, nor Hoffmann's anodyne, nor morphine, nor any other drugs brought relief. The patient was then put on a solution of benzyl benzoate, and after a few doses the condition was completely cured.

CASE III.—A woman suffering from postoperative hiccoughs, under the care of Dr. C. V. W., was treated ineffectually with all ordinary drugs. The condition persisted for over a week, the patient hiccoughing sometimes as often as six to eighteen times per minute. After the ineffectual use of all other drugs, she was put on benzyl benzoate and was relieved within twelve hours.

Not only is benzyl benzoate a useful remedy in the treatment of certain persistent forms of hiccoughs, but, in the author's opinion, it is also of a diagnostic interest in differentiating between the hiccoughs of a purely central origin, on the one hand, and those which are due to some peripheral origin, on the other. Inasmuch as benzyl benzoate exerts its chief effect peripherally on the smooth muscle structures, the author is inclined to believe that this drug may be most useful in the treatment of hiccoughs of peripheral origin.

In administering the drug the author finds the most convenient method to be the one originally described by him in his earlier papers.[3] The benzyl benzoate exerts its action best when given in a 20 per cent. solution in alcohol. Of this solution the patient is directed to take 20 to 40 drops in water or milk. The author has not found it either convenient or advantageous to administer the drug in suspension in various elixirs or syrups, and administration in capsules has been found by him in some case to produce local irritation, and in others to render the therapeutic action too slow. To children the solution can be conveniently administered in sugar water or milk.

It is hoped that this brief note may be helpful to the general practitioner in the treatment of the condition which is not only disagreeable, but may sometimes assume an alarming form.

Medicolegal Notes.

Practising Without License—Indictment Under New York Act Must Name Individual Treated.—On appeal from a conviction of practising medicine without a license in contravention of New York Public Health Law § 161 providing that "no person shall practice medicine unless registered and legally authorized, . . . or unless licensed by the regents and registered," it was contended that the indictment, in addition to charging in the language of section 161 that the defendant unlawfully practised medicine without being registered, etc., should have specified under the language of section 160, defining what practice means, the specific acts performed by him constituting such unlawful practice. In sustaining this contention the New York Court of Appeals says that it is abundantly established that in charging an offense committed upon or in respect of an individual, as diagnosing, treating, or offering to diagnose or treat, a disease, it is necessary to name, or excuse naming by proper allegation, such individual. There is an exception to this general rule that when the crime consists of a series of acts continuous in their nature, such as carrying on a prohibited business, or keeping an unlawful resort, a general description, reasonably including and describing the series, it will be sufficient. It is not necessary, in such cases, to set forth each act going to make up the offense, for, as said in Commonwealth v. Pray, 13 Pick. (Mass.) 359, 362, "It is not each or all the acts of themselves, but the practice or habit which produces the principal evil and constitutes the crime." "In our opinion, however," the Court of Appeals says, "this indictment does not come within that exception. It does not seem to us that the statute was intended to define or constitute the prohibited offense as consisting of a continuous series of acts amounting to the conduct of a business. It may be that if we had nothing but section 161 prohibiting the 'practice' of medicine, and were relegated to the dictionary or common usage for a definition of that word, we should be compelled to interpret it as meaning a continued and habitual performance of acts. But we are not thus left to these means of teaching a definition. Section 160 defines what 'practice' means. Its meaning is satisfied whenever and as often as an individual 'holds himself out as being able to . . . and offers or undertakes to diagnose, treat,' etc. Whenever within the fair meaning of those terms on a single occasion an offender has held himself out as able to and has offered to treat a patient there has been a completed offense, and it is not necessary to show that this operation has been repeated so many times that it has ripened into a habit or business. We think that the indictment and proofs in this case confirm this view. If this is the correct interpretation, there is no question that the individual operated upon should have been named or proper excuse given for not naming him even within what has been said in cases applying the 'business' rule."

Judgment of conviction was therefore reversed and the indictment was dismissed. Three of the seven judges, Messrs. Chase, Cardozo, and Crank, dissented. —People v. Devinny, New York Court of Appeals, 125 N. E. 543.

Testamentary Capacity.—A testator has sufficient capacity to make a will if he has sufficient mind and memory to enable him to understand the particular business in hand, remembers who are the natural objects of his bounty, and can recall to mind his prop and make disposition of it understandingly accor to some purpose or plan formed in his mind.—He Hart, Illinois Supreme Court, 125 N. E. 366.

SUGAR DRESSINGS IN SURGERY.

IT seems to be generally acknowledged that the use of sugar as a surgical dressing has a favorable action on wound repair and granulation tissue. The action of moist dressings made with a 48:1000 glucose serum and the action of dry dressings with powdered glucose should each be considered separately. In the first case the dressings act like any other moist dressing; the quantity of glucose introduced on the wound is relatively very small, since a large number of gauze pads can be moistened with one liter of glucose serum—containing forty-eight grams of glucose. Therefore, glucose serum should be employed only when the patient cannot tolerate glucose in a dry form. Dry glucose dressings have two actions; firstly a physical action; they act in the same way as any inert powder and have the property of mechanically irritating the tissues; but the second, and most important action of powdered glucose is that it feeds the cells to which it is applied, and it is for this reason that it increases cell resistance and activity, consequently increasing local life. Sugar dressings may be correctly termed hyperbiotic and this hyperbiosis is one of supernutrition.

Hyperbiosis can be produced in two ways: thus light will, as we know from a present large experience, improve or cure tuberculous ulcerative processes. Radium in small doses acts similarly and in these lesions injections of soluble salts of radium into the tissues can be used or radiferous ointments or powders may be prescribed, some being indifferent, others both antiseptic and modifying. Electricity and active hyperemia increase the local circulation, fulguration also produces hyperbiosis, but in all these instances it is not a hyperbiosis from nutrition. It would consequently seem clear that their action is only momentary, the cells becoming exhausted after a variable lapse of time according to circumstances. Their nutrition is not increased by these means, but in the case of sugar dressing the cells are actually fed, they are not exhausted herapeutic effect is durable. Saccharose is ilable directly and for this reason glucose referred, as its assimilation is complete. al fact remains that saccharose does give some appreciable results, nevertheless. Such being the case, it may be supposed that the cells, excited by the cane-sugar have furnished a ferment capable of transforming non-assimilable saccharose into glucose and levulose, both of which are directly assimilable. The number of ferments in the human organism is considerable so that this hypothesis can very logically be sustained.

But sugar is an excellent food for bacteria in general, although there are instances in which it has no action on them. Certain observers have even shown that sugar decreases the virulence of some, among them the staphylococcus. Others maintain the contrary opinion and deny any favorable influence of glucose on suppuration. The question is still moot, but at least in some cases, glucose has had an undeniable influence in favoring the development of bacteria in wounds treated with it.

There is an important question to solve, that is, whether a wound in a diabetic patient can be treated with glucose. In these subjects we know the ease with which infectious processes develop; but is the sugar the only factor in their development? Sugar has unquestionably an importance, but other no less interesting factors also play a part. In fact, neuritis and polyneuritis are not uncommon in diabetes, and in this respect should not be overlooked since the experiments of a number of competent observers have demonstrated the influence of nerve division on the localization and development of suppurative processes in the area innervated. The vascular changes arising in diabetes, the hemorrhagic infarcts in the capillaries, may certainly not be without significance in the production of necrosis, gangrene, and suppuration. Finally, in the normal state the pancreas throws a substance into the circulation which modifies the histological structures in the tissues and exercises a marked influence on their nutrition. The suppression of this pancreatic endocrine secretion will result in tissue changes insofar as the nutrition of the tissues is concerned; they lose their reserve materials, since the histolysis is no longer under control and consequently become an easy prey to bacterial invasion. But this is but one point. These materials derived from hystolytic disintegration will react upon the liver, bringing materials to it upon which its glyco-formative activity will act, with the result that hyperglycemia will be the consequence. Then two factors become united which, taken separately, would have had a most marked influence favorable to the development of pathogenic agents, and whose association easily explains the frequency and gravity of infections arising in diabetes. That sugar may be a favorable dressing in diabetic wounds is, therefore, still moot.

In all wounds two very important factors must be considered, namely, the bacterium and the soil. Antiseptic and aseptic dressings have for their object only the destruction of the microbe without taking the soil—the patient—into consideration. In the use of physiological salt solution and other conservative measures, the soil is not disregarded

and the cells are placed in an excellent medium. With sugar dressings the cells are given nutriment so that the soil is all, the bacterium a secondary matter, if it be admitted that sugar favors its virulence, which is denied by many observers. So long as we do not know with certainty the means employed by Nature to overcome infection, such means can only be artificially imitated and the treatment of wounds will remain a moot question until more light is thrown on the subject, even in the advanced state of surgery of to-day and the experiences derived from war.

THE VIRULENCE OF THE PNEUMOCOCCUS.

THE pneumococci were properly classified from the time they were found in all typical cases of pneumonia. Besides the complications of pneumonia, this bacterium produces morbid processes of the serosa and lives as a saprophyte on the mucosa of healthy subjects and animals. Four characters are fundamental and constant: the absence of spores, staining with Gram, a capsule, and immobility. There are others more special, but these may be wanting: the lanceolate shape, the scant and fragile growth on ordinary media, solubility in bile, action on hemoglobin, and a decreasing pathogenic power in mice, rabbits, guinea pigs, and birds. The criterion of agglutination is of little value in identifying this organism. Virulence may be defined as vegetability *in vivo*, and must be distinguished from the toxigenous power, with which it is not necessarily associated. The intensity of experimental infection expresses the relationship between the germs and the resistance of the animal; the virulence is, therefore, estimated by the intensity of the infection and the resistance, necessarily unknown, but supposed to be constant. Only infections of the same clinical type should be compared with each other and, all other conditions being equal, the virulence is estimated by the dose administered and the length of survival. A rigorous estimate of the virulence can be obtained only from bacteria which have never passed through animals. The method of direct inoculation of pathological products should be rejected.

The pneumococcus of pneumonia patients possesses a very unequal activity in respect to mice, and the sensibility of this animal has been exaggerated. The pneumococcus is rarely virulent in the rabbit, but exceptionally it may be very virulent. Pneumococci which are very active for the rabbit will be the same for mice, but when mildly active for the rabbit the activity will vary in mice. A minority of pneumococci killing a mouse will kill a rabbit. A very active pneumococcus for mice may be little so for the rabbit, and when mildly active for mice they are generally inactive in the rabbit. Human pneumococci are only exceptionally virulent in the guinea pig, and this virulence always remains weak. Pneumococci active for the guinea pig are always very active in mice and rabbits; the inverse is not true. Virulent cultures of pneumococci are often scant, fragile, and soluble in bile, and although the latter is inconstant, it is an excellent indication of the species and the virulence, when it exists. The majority of pneumococci active in the rabbit—and *a fortiori* when active in the guinea pig—are soluble. The inverse is not true. Pneumococci inactive in mice are insoluble; those which are moderately or very active are soluble; when very mildly active the organism may or may not be soluble. The solubility in bile may vary in the same sample, in which case the strain is mildly or slightly active for the mouse. Very active pneumococci usually retain their virulence and solubility; but the latter may disappear, yet the virulence remains. There is no necessary relationship between the gravity of the pneumonia and the virulence of the pneumococcus. Even if the resistance of man were known, the virulence for human beings would remain an unknown quantity. The number of pneumococci with which a given case of pneumonia has to deal is unknown, while the relative rarity of the germ in the blood of these patients and the importance of the pulmonary lesions remove human pneumonia from comparison with experimental and true septicemias in mice, which are very exceptional in man. The blood contains few pneumococci in cases of pneumonia, and chiefly when extrapulmonary complications arise.

Cultures of the pneumococcus on physiological gelatine kept in the icebox will retain their vitality for several years, and their activity for mice for several months. Cultures kept in this way and restabbed monthly, will usually retain their full virulence for mice. Only a minority of the germs oscillate around a virulence. Sometimes this oscillation can be followed—a disappearance and reappearance of the virulence taking place. A study of numerous passages through three species of animals shows that very active pneumococci for mice—their virulence is always stable for this animal—and very active pneumococci having a stable virulence for the rabbit remain the same during their passage through the three species. Pneumococci little active for mice, or at the limit for the rabbit and guinea pig, cease to progress by passage through animals. Pneumococci little virulent for the guinea pig never increase in virulence, no matter which species of animal is used for passages. Pneumococci which are very active for the rabbit, but with a fragile virulence, will, according to the species used for passages, more or less completely recover the activity they possessed when taken from the human organism and which had rapidly decreased.

THE PHYSIOLOGY OF THE THYMUS GLAND.

THE first experimental excision of the thymus gland was done by Estellí in 1845, on dogs, sheep, and calves, which died after a short febrile period. In 1848 Friedleben undertook experiments on twenty-three dogs, all of which tolerated removal of the thymus, so that this observer concluded that the removal of this gland had no more effect upon the

future survival of the animal than removal of the spleen. It is of interest to note that after thymectomy, Friedlaben's dogs offered changes in the bones in respect to the richness of the vascular supply, flexibility, and delay in growth. Almost forty years later Tarulli and La Monaco found by their experimental work that the thymus is not an organ which is essential to life. Very young thymectomized dogs presented muscular weakness, a diminution of the blood mass, and changes in the bones similar to those in rickets. These disturbances disappeared with the growth of the animal. In 1903 Bosch showed that excision of the thymus done by the majority of observers had been incomplete, and in his opinion the dog was most sensitive to removal of this gland. Since the thymus of dogs undergoes a rapid involution from the second month of life, Basch used very young pups, still suckling, and in them he especially met with changes in the bone—delayed ossification and spontaneous fractures. Besides, he noted a decrease of the intelligence, as well as a change in the psychic state of the animals.

More recent observers, Klose and Vogt, experimented on fifty-four dogs ten days old, and following thymectomy they noted three phases: (*a*) a latent phase; (*b*) a phase of adiposity extending from the second to the third month following thymectomy, and (*c*) a phase of thymoprivous cachexia and thymoprivous idiocy occurring in the thirteenth to the fourteenth month. Still more recently, Matti noted that following thymectomy on very young dogs there was a delay in growth, with softening and inflexion of the bones of the limbs and tumefaction of the epiphyseal region. Other changes consequent upon thymectomy were related to changes in the calcareous metabolism, changes in the figured elements of the blood and hemoglobin, in the central nervous system, the spleen, and pancreas, as well as changes in the various endocrine glands, particularly the thyroid, suprarenals, genital glands, and hypophysis.

Intravenous injections of thymus extracts produce, according to Olivier and Schaefer, a fall in the blood pressure due to a substance probably closebe related to choline. Essays at hyperthymization by injections of thymic extract produced symptoms of intoxication with fever, muscular contractions, and a comatous state. After gastric ingestion of a calf's thymus in dogs, Minkowsky noted in the urine of these animals an organic acid at the time unknown, but closely similar in composition to uric acid. Parisot obtained a fall in the blood pressure by injecting thymus extracts in normal children; they obtained the same fall by the use of extracts of lymph nodes.

Experiments on hyperthymization have been carried out by Ranzi and Tandler, who injected extract of sheep's thymus into sheep and following this, they noted an arrest in the growth of the animal; Charrin and Ostrowski, after treating dogs for three to four months with thymus extract, noted the appearance of bone deformities. One practical point to be noted is that up to the present time no averred symptoms of thymoprivous cachexia has ever been observed in the human subject after thymectomy. This fact can be readily understood when it is recalled that the total excision of the gland is difficult to carry out, and on the other hand a very small bit of thymus may regenerate a neothymus capable of assuming all the endocrine functions of the primary organ.

Is Ambidexterity Advisable?

Regnault asks in *La Presse Médicale* for April 21, 1920, xxviii, 24, if it is advisable that one make himself ambidextrous. Plato, Aristotle, and Marcus Aurelius believed that the left hand is defrauded of its birthright by a certain negligence and that it is a duty to restore its equality. Franklin once wrote a whimsical "petition of the left hand to those who superintend the education of man." The same view is held by many physiologists to-day. Nevertheless there is something to be said on the other side. It may be asserted that the work of the left hand is different from that of the right. We need one free hand and one to carry luggage or equipment and hence the right is used for emergency while the left is continuously occupied. Emergencies call for rapid and skilled actions so that the right hand specializes in these, the left arm having the greater endurance. "The right arm is the dynamic, the left the static arm." The left arm is also a reserve arm when the right has become exhausted. It is very difficult to train the left hand to execute rapid, complicated, and delicate maneuvers, but it can sometimes readily reverse the movements customary for the right hand, as in mirror writing. Hence it would appear that to some extent the education of the left hand should consist not of copying the activities of the right but of reversing them. True ambidexterity would seem to imply teaching the left hand to execute individual movements entirely distinct from those of the right so that the individual can perform two radically different tasks at the same time. Taylor, the American efficiency engineer, advocated the cooperative use of the two hands in a single task along strict efficiency lines, in that both hands could be busy at the same moment, and this appears to be the gist of ambidexterity in practice.

Chloroform Syncope Averted by Direct Heart Massage.

Dr. Petti of Buenos Ayres (abstract from *La Semana Medica* in the *Revista Medica Cubana*, November, 1919, xxx, 11), had under his care a woman of 54 who suffered from an undetermined gastric affection. An exploratory laparotomy was therefore undertaken because of the urgency of the symptoms, and by means of the Roth-Drager apparatus 200 drops of ether and 60 drops of chloroform per minute were inhaled for some minutes. When anesthesia was complete, the incision was made, but no blood flowed and patient was found to be pulseless. Artificial respiration brought no positive resule and caffeine was thrown in both subcutaneously and intravenously, also without returns. The diag-

nosis was now made of primary chloroform syncope, and having obtained the sanction of his colleague Galindez, the laparotomy incision was extended by Petti and the hand introduced for the purpose of transdiaphragmatic massage of the heart. That organ was felt to be quite flaccid and bimanual squeezing was at first without response. All at once a powerful contraction was felt, followed irregularly by others, the massage being maintained. At the end of thirty seconds it was tentatively suspended, but it at once became necessary to resume it. Contractions reappeared and with the resumption of massage artificial respiration and tongue traction were added with oxygen inhalations. Massage was not discontinued again until the subject was out of danger. Although the thoracic organs had begun to function normally, the patient was still unconscious from the anesthetic, and this condition persisted long after the physical effects of the anesthesia had worn off. Recovery was delayed by violent delirium necessitating a straight jacket and morphine. The case is believed to have been the first to occur in Argentina of resuscitation from true cardiac syncope.

Lethargic Encephalitis in the Past.

Durodié of Bordeaux, who wrote entertainingly of the antiquity of pandemic influenza some months ago, has been investigating the past for traces of lethargic encephalitis, according to an abstract in the *Progrès Médical* for April 17, xlviii, 16. In Celsus he finds an account of lethargic fever in which high fever and irresistible tendency to sleep were the main symptoms. This affection, whatever it was, was apparently curable by vigorous treatment directed to the cranium—cold applications and revulsives. Nothing more was found until the description of a somnolent fever by Sydenham already noted in the editorial columns of the Medical Record. Over a century later Stoll described what comes nearest to the modern type of the disease, for in one of the cases the subject had not only high fever, somnolence and headache, but diplopia is actually mentioned. An autopsy was performed and it would seem that some meningitis must have been present, although meningeal symptoms are not mentioned during the life of the patient. A still better account from the modern viewpoint was published some years later by Finot. The patient recovered and despite the parallel with the modern case there were also symptoms pointing to meningitis. In 1802 Pinel describes under "slow, nervous fever" a condition which in many respects corresponds to lethargic encephalitis. He takes the term from Huxham, but adds the adjective malignant to characterize the type in question. Rigidity of the muscles of the limbs is one of the symptoms mentioned and one can also make out eye symptoms and myoclonus from the symptomatology. The term lethargic encephalitis was actually used by Franck in 1837 and this author definitely ascribes the disease to epidemics of grippe. The symptomatology is not satisfactory, however, for no eye symptoms are described beyond conjunctival injection and staring look. Durodié concludes that the disease is not new and has always been present off and on. He fails to mention Dubini's electric chorea.

News of the Week.

Blindness in Saharan Oasis Towns.—A medical examination conducted on behalf of the American Red Cross in Algeria and Tunisia recently disclosed the fact that in the oasis towns of the Sahara 10 per cent. of the native population is blind, whereas in France there are only three blind persons for each thousand inhabitants. It showed, too, that the present epidemic of trachoma has made its greatest headway among the younger children, both European and native. At Boufarik 27 per cent. of the European children and 56 per cent. of the native are affected; at Marengo 33 per cent. of the Europeans and 57 per cent. of the natives. Of 6,025 children examined in different parts of Algeria, 1,650, or 24 per cent., were trachomatous. In the large half-European half-native towns along the Mediterranean, 25 persons in each thousand are blind. Dr. Edmond Sergent, Director of the Pasteur Institute of Algiers, in one small settlement in the department of Oran, found 156 trachomatous cases among a total of 236 inhabitants.

Marsh Plagues Menace Italian Charcoal Burners.—According to the Italian and American Red Cross doctors who have been investigating the large number of deaths which have occurred within the last few months among the Italian charcoal burners in the district about Cittâ di Castello, the universal diet of polenta and life in the unhealthy marshes surrounding the town were contributory causes, while pellagra, malaria, and influenza were found to be the direct causes.

American Nurses Wanted in South America.—Miss Agnes S. Ward, superintendent of nurses in the New York City hospitals, has received appeals from Rio Janeiro and Bogota for five hundred women to establish training schools for nurses in South America.

Malaria in Georgia.—For many years malaria has caused a loss of six million dollars, and, among the negroes alone, a loss of over a million and a half working days each year in South Georgia. It infects from 20 to 100 per cent. of the people in the communities, and causes the death of 800 people yearly. Recently the American Red Cross, in cooperation with the State Board of Health, the Georgia Association, the U. S. Public Health Service, and several large corporations, has undertaken an extensive anti-malaria campaign. Moving pictures, lectures and the press have all been utilized in calling the attention of the people to the importance of destroying the mosquito and all its breeding places.

Finger-Prints from Cradle to Grave.—The suggestion has been made by Deputy Police Commissioner Joseph A. Faurot, the finger-print expert of the New York City Police Department, and Acting Captain John H. Ayres, head of the Bureau of Missing Persons, that doctors filing birth certificates be required also to file finger-prints of the new-born baby. This would require a change in the Sanitary Code.

Police Hospital in Brooklyn.—A campaign is to be inaugurated in the near future to raise a fund of $5,000,000 for the purpose of building a hospital of 300 beds for the Police Department. Brooklyn was selected for its location because land is cheaper there than in Manhattan. It is intended to spend

about $800,000 for a site and $2,500,000 for the building and equipment. The balance of the $5,000,000 will be used to establish an endowment $250,000.

Mobile Loses Fight for College.—The Supreme Court of Alabama has decided against Mobile in the matter of the removal of the Alabama Medical College from that city to Tuscaloosa. This decision is said to be final, and presumably closes this hard-fought battle between medical factions and citizens of Alabama.

The Bronx County Medical Society recently announced that it is not supporting the agitation by certain physicians in behalf of the Bronx physician who was recently convicted of manslaughter in connection with the death of a woman patient upon whom he was charged with having performed an "unnecessary operation"—curettage.

Dispensary Service.—The endowment fund committee of the New York Post-Graduate Medical School and Hospital, in connection with the drive of that institution to obtain a two million dollar fund, has made the following tabulations of the total number of visits made last year to six large non-municipal dispensaries in New York City and to the largest dispensary in Boston: Post-Graduate, 173,285; Presbyterian, 67,818; St. Luke's, 65,895; New York, 65,283; Roosevelt, 54,010; Mount Sinai, 189,959, and Massachusetts General, Boston, 152,025. About 4,000,000 visits are made to the dispensaries of New York City each year.

The Yellow Fever Germ.—It is reported from San Salvador that Dr. Salvador Peralta Lagos, a prominent bacteriologist of that city, has isolated a microorganism in yellow fever which presents the morphological and cultural characteristics of the one discovered in Guayaquil by Dr. Hideyo Noguchi of this city.

The Board of Scientific Directors of the Rockefeller Institute for Medical Research recently elected Dr. W. J. V. Osterhout to succeed the late Dr. Theodore C. Janeway as a member of the board. The following promotions and appointments were announced: Dr. Alfred E. Cohn, hitherto an Associate Member in Medicine; Dr. Peyton Rous, an Associate Member in Pathology and Bacteriology, and Dr. Donald D. Van Slyke, an Associate Member in Chemistry, have been made members; Dr. Francis G. Blake, hitherto an Associate in Medicine, and Dr. John H. Northrop, an Associate in Experimental Biology, have been made Associate Members, and Dr. James H. Austin, an Assistant in Medicine; Dr. Harry W. Graybill, an Assistant in the Department of Animal Pathology, and Dr. William C. Stadie, an Assistant in Medicine, have been made Associates. The following have been made Assistants: Miss Helen L. Fales, Chemistry; Dr. Philip D. McMaster, Pathology and Bacteriology, and Miss Marion L. Orcutt, Animal Pathology.

New York State Civil Service Examinations.—The New York Civil Service Commission announces the following examinations, to be held July 31, for: Assistant in Neuropathology, at a salary of $2,160; Associate in Bacteriology, at $2,360; Associate in Internal Medicine and Clinical Pathology, at $2,360; Senior Physician, at $2,000. The positions to be filled are at the Psychiatric Institute, Ward's Island, New York City.

Opposed to Compulsory Health Insurance.—At the closing session of the seventy-sixth annual convention of the American Institute of Homeopathy, held in Cleveland, in June, steps were taken to combat all compulsory health insurance and to wage a campaign to secure recruits in the field of Homeopathy.

Campaign Against Malaria.—In reviewing the work of the Rockefeller Foundation during 1919 President George E. Vincent states that in June, 1919, a conference was held to plan a concentrated campaign against malaria in the Southern States. Representatives of the United States Public Health Service and of the International Health Board of the Rockefeller Foundation were present, and these men worked out a program which was subsequently approved and adopted in ten Southern States. Funds for malaria control operations, he says, are now being appropriated faster than sanitarians can be found to do the work. From the outset the Foundation's International Health Board has entered an area only at the invitation of the Government concerned, its work being based upon the considerations of cooperation with the authorities, the community's assumption of some part of the expense, and an agreement that if the experiment is successful the Government will take over the enterprise as part of its official machinery. It is estimated that 8,000,000 people are within the malaria area covered by the southern part of the United States, Mexico, Central America, the West Indies, and the northern countries of South America.

Prizes for Anesthesia Research.—The National Anæsthesia Research Society has announced prizes aggregating $200 for the best papers on anesthesia research.

Lake Keuka Medical and Surgical Association will hold its twenty-first annual meeting July 29 and 30 at Keuka, N. Y., under the presidency of Dr. Alfred W. Armstrong of Canandaigua.

Miss Julia C. Stimson of New York City has been appointed by Secretary Baker as superintendent of the Army Nurse Corps, with the relative rank of Major. Miss Stimson, who was graduated from the New York Hospital Training School for Nurses, was chief nurse of the American Red Cross in France, and later director of the Army Nurse Corps, A. E. F. She received the D. S. M. and the British R. R. C.

Dr. Serges Voronoff of Paris, who is known for his advocacy of testicular grafts for the rejuvenation of the aged, has arrived in this country. The newspapers report that he wants to use the "interstitial glands" of men rather than monkeys, and in the absence of volunteer donors is hoping that there will be some electrocutions soon whereby he may obtain material.

Medical Society Elections.—THE RHODE ISLAND MEDICO-LEGAL SOCIETY, at its annual meeting held at Providence in June, elected the following officers for the ensuing year: *President,* Henry D. C. Dubois, Providence; *Vice-President,* Dr. Roswell S. Wilcox, Providence; *Secretary-Treasurer,* Dr. Harry S. Flynn, Providence.

THE WOONSOCKET (R. I.) DISTRICT MEDICAL SOCIETY, at its meeting held June 23, elected the following officers for the coming year: *President,* Dr.

R. G. Reed; *Vice-Presidents*, Dr. A. A. Weeden and Dr. W. C. Rocheleau; *Treasurer*, Dr. A. Constantineau; *Secretary*, Dr. T. F. Baxter.

THE NEW BEDFORD (Mass.) MEDICAL SOCIETY, at its recent meeting elected the following officers for the ensuing year: *President*, Dr. Frank M. Howes; *Vice-President*, Dr. Samuel K. Segall; *Treasurer*, Dr. Charles S. Lipsett; *Secretary*, Dr. Charles Shanks; *Recording Secretary*, Dr. Charles C. Persons.

THE NORTH CAROLINA MEDICAL, DENTAL AND PHARMACEUTICAL ASSOCIATION, an organization of colored physicians, dentists, and pharmacists, held its thirty-first annual session recently at Rocky Mount. The following officers were elected for the ensuing year: *President*, Dr. W. C. Strudwick, Durham; *First Vice-President*, W. H. Williams, Goldsboro; *Second Vice-President*, B. J. Burnett, Rocky Mount; *Secretary-Treasurer*, Dr. Clyde Donnell, Durham.

THE OKLAHOMA HOSPITAL ASSOCIATION at a recent meeting held at Oklahoma City elected the following officers: *President*, Dr. Fred S. Clinton, Tulsa (re-elected); *First Vice-President*, Dr. J. A. Hatchett, El Reno; *Second Vice-President*, Dr. A. J. Risser, Blackwell; *Executive Secretary*, Paul J. Fesler, Oklahoma City; *Treasurer*, Dr. J. H. White, Muskogee.

THE SOUTH DAKOTA STATE MEDICAL ASSOCIATION, at its thirty-ninth annual session held recently at Sioux Falls, elected the following officers for the coming year: *President*, Dr. H. T. Kennedy, Pierre; *First Vice-President*, Dr. G. S. Adams, Yankton; *Second Vice-President*, Dr. G. G. Cottam, Sioux Falls; *Secretary-Treasurer*, Dr. Frederick A. Spafford, Flandreau.

Charitable Bequests.—By the terms of the will of the late Mrs. Luisa de Navarro of New York City it was provided that the bulk of her estate shall be used in establishing a hospital in this city for needy Spanish-speaking peoples. One share each of her residuary estate was left for the work for the blind and the work for the deaf and dumb in Mexico City.

The Bowdoin Medical School has received notice that the late Dr. Frank Byron Brown of Boston, of the Class of 1887, has bequeathed to the school one thousand dollars.

Obituary Notes.—Dr. ISRAEL ALBERT LOVELAND died suddenly at his home in Keene, N. H., July 5, at the age of seventy. He was graduated from Dartmouth Medical School in 1875 and practised in Westmoreland and Gilsum counties until his retirement in 1909. He was a member of the American Medical Association.

Dr. WALTER W. SCOFIELD of Dalton, Mass., died July 6 at the age of sixty-six. He was graduated from the Albany Medical College in 1882. He was a member of the American Medical Association.

Dr. ERNEST K. PARKER of Springfield, Mass., was found dead in his office July 9.

Dr. THOMAS J. BUCHANAN of Toms River, N. J., died July 15 from the effects of *x*-ray burns received fifteen years ago. Dr. Buchanan, who was sixty-one years of age at the time of his death, was graduated from Jefferson Medical College, Philadelphia, in 1889, and was one of the pioneers in the study of the *x*-ray in the treatment of malignant growths. Five years ago he established the Toms River Hospital, but continued his connection with Jefferson Hospital, to the service of which he had long been devoted. He was a member of the American Medical Association and of the Medical Society of the State of Pennsylvania.

Dr. MATHILDA ANNETTE PELHAM died at her home in New York City July 16. She was graduated from the New York Medical College and Hospital for Women in 1900, and was a member of Homeopathic Medical Society of the State of New York.

Dr. CHARLES W. BRANDENBURG of New York City died July 17 at the age of sixty-nine. He was graduated from the Eclectic Medical College of the City of New York in 1891, in which institution he taught for many years.

Correspondence.

PELLAGRA AND THE "SORE MOUTH" OF DOGS.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—In 1884 I had a very close friend living in Galveston, Texas, who had a malady that baffled the skill of our best medical talent. He died. Just what his death certificate stated as to the cause of death I know not, and it matters little, for each physician consulted differed from the preceding one as to the nature of his disease. Some twenty-five years afterward pellagra was found to be prevalent in this country and it was only then that I became convinced just what my friend died from.

As a physician now I am seeing and treating many cases of pellagra, and I want to say that I am not willing to accept what has been stated as to the etiology. My friend of 1884 had lived a life of ease and had lived pretty much all his life on a diet that Goldberger has recommended as preventive or curative, yet he contracted the disease and died when it was unknown in this country.

Again, I have seen the disease treated and I have seen treatment refused, and as an observing man I am inclined to the belief that the one does as well as the other. You let a well informed practitioner practise in a community where it exists and I think he will draw the same conclusions, unless he has a conceited ego as to himself or his remedies.

Now for a little story to be taken for what it is worth: Some five years ago I bought a very fine dog in New Jersey and brought him to Texas. The second year in Texas he died with what the veterinarian pronounced "sore mouth." Now, a dog dying with sore mouth was as novel to me as was a man dying with pellagra. I noticed that my dog was losing hair from his front legs (paws). In commenting on the cause of my dog's death with my friends I find that it is a relatively common disease, and that there is a large strip of country east of town on a branch called the Tehuacana where they cannot have dogs, as they all die of the sore mouth. Now, this strip of country has furnished some 40 or 50 pellagrins to the nearby doctors for treatment. The question is, how much the dog plays in the etiology, or are they both, man and dog, infected from the same source, or is the

sore mouth a different disease and is it a coincidence that they are found here side by side?

M. B. SAUNDERS, M.D.

WACO, TEXAS.

THE TWO CLASSES OF PHYSICIANS.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—It hardly seems to me that the contributor of the article, "The Two Classes of Physicians," in your issue of June 26 has shown a proper appreciation of the viewpoint, nor a proper respect for, or valuation of the personality of the contributor of the article, "Some So-called Advances in the Practice of Medicine," of your issue of June 5, in his recent rejoinder.

It certainly would not seem just to place Dr. Beverley Robinson, in the category described as, "those who do not care to make accurate diagnoses but by their presence at the bedside, give patients a false sense of security, thereby depriving them of efficient medical aid, or often deferring it until the patient's life is endangered," etc.

To many of us who have borne the heat and burden of the day, such wholesome reflections as come from the mature pen of Dr. Robinson, who has so long practised the art as well as the science of medicine, are refreshing as free from the cant of much that in modern medicine is pure gallery play, and we recall with affectionate remembrance the bedside assurances of comfort as well as security that came from the sympathetic as well as sincere personalities of the many men who were Dr. Robinson's confrères of the old school, none of whom I am sure could have been put in the classification referred to, to those who deserve such classification, Dr. Robinson's reflections in no way refer.

J. B. CUTTER, M.D.

147 BUENA VISTA AVENUE,
SAN FRANCISCO.

OUR LONDON LETTER

(From Our Own Correspondent.)

LONDON, June 27, 1920.

Meeting of the British Medical Association.—By the time this letter is published the eighty-eighth annual meeting of the British Medical Associaion will have come and gone. As a matter of fact, the representative meeting begins in the Examination Halls at Cambridge to-day. The meeting proper commences on Tuesday, June 29, under the presidency of Sir T. Clifford Allbutt, who will deliver his address on that day, preceding the meetings of sections. The annual dinner will be held in the Hall of St. John's College on the evening of July 1. The popular lecture will be given by Dr. G. S. Graham Smith, F.R.S., on "Flies" on July 2. Laboratory and clinical demonstrations will be given on three consecutive days from 2.30 to 4.30 P. M., commencing on June 30.

The scientific business of the meeting will be conducted in twelve sections, which will meet on the days indicated from 10 A. M. to 1 P. M., the demonstrations following in the afternoon.

The meeting of the Association promises to be one of the most successful ever held from the points both of view of attendance and of the importance of the subjects discussed. Cambridge is a convenient place in which to hold it and a great asset of the meeting is the choice of president. Without hyperbole Sir T. Clifford Allbutt may be termed the grand old man of the British medical profession. He is a speaker of rare aptitude and eloquence and in every respect adapted for the position of president.

Ex-Service Men Suffering from Tuberculosis.—The Minister of Pensions has considered the recommendations of the Inter-Departmental Committee on Tuberculosis, 1919. He has, as a result decided that men suffering from pulmonary tuberculosis, which is admitted to be attributable to or aggravated by service, and who on the conclusion of treatment in a sanatorium, undergo a prescribed course of extended treatment, combined with training in a training colony, shall be granted pension at the 100 per cent. rate for six months from the date of leaving the colony, and thereafter at the rate corresponding to the degree of disablement, but not less than 50 per cent. throughout the subsequent period of two years. The award will be subject to the condition that the pensioner presents himself when required in order that the Ministry may be advised as to his condition from time to time, and as to the need for further treatment. The arrangement will apply also to the pensioner who is not recommended for a further course in a training colony, the 100 per cent. pension in his case commencing as from the date of his discharge from the sanatorium.

Tuberculosis and the Workers.—At the Tuberculosis Congress held in Leeds and which was opened on May 13 last Dr. A. Trimble of Belfast said he believed tuberculosis was not caused so much by the actual industrial occupation of the workers as by the terms and conditions under which, and the wages for which they worked. Infection, unless from a massive dose, did not take place to any appreciable extent after childhood. Comparing the tuberculosis rates in England and Ireland, he ascribd the lower figures of the former largely to better education. In Belfast, where women were employed industrially in large numbers, the female death-rate from tuberculosis had always been as high as that of the male. It was not purely a war phenomenon. No woman should be expected to work in both home and factory. Workers should not wait until the classical features of consumption were forced upon their attention, but should look out for tiredness and loss of appetite. Then if only the tired worker could get proper rest, though no doctor or nurse went near him, or her, probably 90 per cent would be automatically cured. Professor Benjamin Moore said that while he did not wish to stand as a strong protagonist in favor of the infection side of the problem, it was necessary to remember that Pasteur and Koch had lived. The cost of making healthy all those invalided by tuberculosis would be a sound piece of expenditure. Since more people died at fifty of tuberculosis than at twenty he was convinced that many picked up the infection in the workshop. The textile workshops, where still air was necessary, were particularly risky in the matters of infection and depressing

effect, because of the difficulty of ventilating them properly. He was convinced that workshop conditions themselves were quite twice more detrimental than all the other evils of city residence taken together. Colonel Nathan Raw, M.D., M.P., pointed out that tuberculosis is never an inherited disease, but always an infectious one. The tuberculosis problem was a social one. The energy of the state must be chiefly directed toward prevention. The reason why sanatorium treatment under the Insurance Act had not come up to expectations was largely the shortness of stay in these institutions, this being due to the fact that they were frequently dull and uncomfortable places. The Government now proposes to set up ten village settlements where consumptives can live for years with their families and work at suitable occupations as far as they are capable. Preference would be given to ex-soldiers and sailors, who would be given full pensions for the first year. Afterwards, when at work they would receive the full rate of wages for the number of hours they could work, which on the average was about 50 per cent. of what a heatlthy man could do, and these wages would be supplemented by an ample subsidy.

The Number of Panel Patients Allowed to One Practitioner.—The Middlesex Insurance Committee decided recently that a doctor employing a permanent assistant should be allowed to have 5,000 panel patients. The regulations allowed maximum of 3,000 panel patients per doctor. If he had a partner they could have 5,000 on the list and the committee thought that if a doctor employed an assistant he should be allowed 2,000 extra patients, making the total 5,000. In reply to criticism that the number was too large, Mr. Cooper said it had been found that the larger the panel the more satisfactory was the attention they received.

2. Progress in Surgery. E. H. Risley.

1. Prostatectomy.—H. G. Bugbee holds that any surgical procedure of import passes through three stages in its development: *First*, the recognition of a pathological condition, and preliminary crude attempts at its relief; *second*, widespread experimentation, the discovery of a pathological entity, the presentation of numerous operative procedures, and the ultimate formation of a fundamental surgical foundation; *third*, crystallization, definitely placing the operature procedure in the realm of surgery, where it will stand as a logical and sound method of relief, to be modified from time to time, but remaining essentially the same in principle. The operative relief of prostatic obstruction of the vesical neck presents an admirable example of these steps, the history of which is given in the more important details. It is doubtful if any other surgical procedure will ever have such an interesting and striking history in its development, for the progress in the treatment of this class of cases has accompanied and possibly has largely accounted for the placing of urology upon a definite footing as a special branch of surgery. Unquestionably diagnosis is responsible. The possibility of studying the urinary tract as an entity and its relation to the human organism gave the true light to vesical obstruction, and made the second stage of its surgical development possible. The third stage has now been reached. The writer classifies the cases that fall within the realm of surgery—and these are the majority—as fibro-adenomatous hypertrophy, fibrous prostate, carcinoma, and muscular hypertrophy. The first and most important step in the handling of a prostatic case is unquestionably the diagnosis of the lesion, which cannot often be made at one examination. The immediate indication is to remove the urgent symptoms, which requires excellent judgment. A patient should be prepared for examination by slowly relieving the pressure, increasing elimination from the bowels, regulating the diet, and employing urinary antiseptics. When the local and vesical congestion has been sufficiently reduced, a cystoscopic examination is made. The intravesical surface of the prostate, as well as the bladder, should be studied in every case where it is possible to pass an instrument. Delicate manipulation is essential. Rectal palpation with the bladder empty is essential, and palpation with the cystoscope in position gives a very definite idea of the amount of intervening tissue. The patient as an individual must be studied—his medical history, habits, environment, general physical examination, and lastly, his urological condition, must be taken into account in order to give him his just due. The diagnosis having been made, the next step is to increase elimination by improving the drainage of the urinary tract. (The further discussion of the subject will be given in a subsequent issue of the *Journal*.)

7. Vomiting from a Surgical Viewpoint.—A. Wiese Hammer considers vomiting as often a cardinal symptom of the first magnitude. He attempts to dispel the too frequent thought that vomiting is an unimportant symptom, and to point out the importance of using care in the interpretation of all cases of vomiting, suggesting that where the causes are not plainly indicated an investigation should be made of every organ and bodily function so as to determine the true cause of this important symptom.

3. The Factor of Fever in the Diagnosis of Cancer.—W. Gordon calls attention to this uncommon accompaniment of cancer, the chief importance of which depends on the liability to forget it. If fever be forgotten, cancers may be diagnosed as inflammatory lesions, and inflammatory conditions secondary to cancers may have their cause overlooked. The practical problems which present themselves in connection with fever in cancer are three: (1) If fever is present, is it caused by uncomplicated cancer? (2) If cancer is present and fever also, is the fever due to the cancer itself or to some inflammatory complication? (3) If an inflammatory lesion is present, causing fever, is cancer also present? Despite teaching to the contrary, cancer is not necessarily the afrebile condition it has so generally been believed to be. There is now evidence that rapidly growing cancers, such as round-celled sarcomata and the softer varieties of carcinoma, in certain organs, can cause fever in the absence of an inflammatory complication. This seems to be the case in six situations at least, viz., in the liver, stomach, suprarenals, long bones, lungs with mediastinum, and breast, precise evidence being limited to cancer of the liver, the stomach, and the long bones. The writer denominates this fever of cancer uncomplicated by inflammatory lesion as "growth fever," a name which only commits one to the assumption that the fever is produced by some process of the growth itself, apart from inflammation; and the fever caused by any inflammatory complication of a cancer he calls "complication fever." "Growth fever" has hitherto been explained as "due to the rapid growth and multiplication of the cells," to "an extreme activity of cell growth." While this may well be the cause, there are other possibilities to be considered. It has been suggested that in a rapidly growing cancer the vitality of the new cells is low, and the fever may be due rather to absorption of dead material than to activity of growth. Another suggestion which has been offered is that, as in rapidly growing cancer hemorrhage is common, the absorption of this blood may account for the fever. Gordon classifies cancers according to the type of fever occasionally found in conjunction therewith, as: A. *Either growth fever or complication fever.*—Liver, stomach, suprarenals, lung with mediastinum, long bones, breast (rarely). B. *Complication fever only*—Gall-bladder, bile-ducts, large intestine, appendix, uterus, fallopian tubes, ear, glands in neck, tongue, lip, esophagus, pancreas, peritoneum, rectum, eye, larynx, thyroid. C. *Neither form of fever.*—Kidney, vulva, testis, penis, urethra, parotid, jaw, brain, spine, skin, muscles, heart, and pericardium.

4. Cerebral Reactions Following Injections of Novarsenobenzol.—Frederick G. Hitch presents the histories of two typical cases. Both patients were well-developed young adults, apparently healthy except for their specific infection, and presented neither in their past history nor present physical condition any of the recognized contraindications to arsenical treatment; both developed the usual symptoms of epileptiform convulsions and coma, and both terminated fatally. The study of these cases convinces the writer that the widespread capillary hemorrhages, demonstrated by microscopic sections, afford a clear anatomical basis for the hypothesis put forward (by Surgeon Commander Dudley) that the symptoms are due to anoxemia, that this anoxemic condition is mainly produced by interalveolar hemorrhage into the lungs, and to a less extent by interstitial capillary bleeding into other organs, and that the *continuous* administration of oxygen (as carried out by Surgeon Lieutenant Commander Parnell) offers the best hope of recovery in these unfortunate cases.

2. The Commoner Complications of Bacillary Dysentery in Military Practice.—Philip Manson-Bahr reminds the reader that the complications of bacillary dysentery have received scant attention from medical writers in the past, and proceeds to consider some of the complications which have arisen, since the recent campaigns in the East, apparently due to the absorption of the toxins of the *Bacillus dysenteriae*. Of these complications, monarthritis, or more generally polyarthritis, have been frequently noted during the Egyptian and Palestine campaigns. The majority of the cases of arthritis encountered during the course of bacillary dysentery have been those previously injected with antidysenteric serum, though arthritis was observed twice in cases untreated by serum of any kind. From personal observation the writer classifies arthritis occurring subsequent to the administration of antidysenteric serum, either by the subcutaneous or the intravenous route, under the two headings: (1) Fugitive polyarthritis, with or without joint effusions, occurring during the course of "serum sickness." (2) Intractable polyarthritis, with effusion into joints and wasting of adjoining muscles, apparently due to absorption of dysenteric toxins. He mentions such infrequent complications as iridocyclitis and parotitis. It is reasonable to suppose, he holds, that there exists an idiopathic dysenteric arthritis due to the absorption of specific dysenteric toxins from the bowel wall and their excretion (as is known to be the case during the absorption of toxins of septic and gonorrheal origin) into the joint cavities. In the same manner the arthritic symptoms occurring during the course of serum sickness may be justly regarded as

representing an effort on the part of the organism to rid itself of toxins peculiar to horse serum; and it is possible that a particularly high percentage of these toxins, even when introduced in moderate doses into a subject already suffering from dysentery in which *per se* arthritis is not an infrequent complication, may not only determine the onset of the condition, but also the amount of disintegration of the joint thus produced.

3. Instinct and Hysteria.—V. T. Carruthers, in a brief discussion of this subject, expresses the opinion that men and animals alike are swayed by a purposive impulse in their fundamental activities, and this impulse, or teleological striving, can be studied in the conative aspect of the instincts. In many animals instinctive behavior consists in quite simple reactions, but one also finds animals, especially insects, in which the behavior is extremely complicated. One does not know in the least how this complexity of animal behavior is produced, but there is reason to believe it is due to something different from human intelligence. In man the complexity of his instinctive behavior is due partly to intelligence and partly to the same cause that modifies the primitive responses of the animal. It is here suggested that certain functional diseases often represent the modified conative activity of primary instincts—especially of flight, self-abasement and self-display; and that "hysteria" is an example in man of the complications, which conations, originally simple, are known to undergo in animals.

1. On the Passive Mechanical Factor in Heart Disease.—Alexander Blackhall-Morison defines the "passive mechanical factor in heart disease" as the conditions which promote or impede the effective exercise of the active factor—the cardiac muscle. The matter so defined is, obviously, both physiological and pathological. The combination of exocardial and endocardial passive mechanical factors finds a place in many cases of heart disease—in some the one class and in others the other preponderating. The management, therefore, of the problems involved is, like the factors themselves, one which combines dealing with both. Thus the thoracotomy or other method used for the removal of exocardial impediment may be necessary to the successful treatment, by appropriate agents, of disorders due to or aggravated by defects of passive endocardial factors. In considering the passive exocardial factors, it was found that to influence beneficially the action of the cardiac muscle it was necessary to deal with impediments to its action outside the heart itself. In treating the endocardial passive factor it can be influenced only by action upon the cardiac muscle and the blood content of the heart. In the management of the passive mechanical factor in heart disease, a maintenance of efficient respiration is of the first importance. One of the earliest evidences of imperfect circulation through the heart is some degree of embarrassment of respiration, of what has conveniently been called breathlessness and technically dyspnea. Regardless of its degree, the condition has to be dealt with on three lines, namely, by posture; in certain cases by rhythmical manual expiratory pressure and it may be also by manipulatory inspiration, in short, by artificial respiration; and by strychnine. As regards the blood content factor, no one can have removed a large clot from one of the chambers of the heart *post mortem*, and witnessed its immediate shrinkage from elasticity, without being struck with the importance of this mechanical factor in dealing with the engorged heart. This effect, naturally, is most evident in the thinner and more distensible auricle, in which the shrinkage reminds one of the contraction of the uterus after removal of the placenta or of blood clot. With such cardiac dilatation during life valvular incompetency frequently occurs, although even this has been denied by some. While direct cardio-puncture, which has been called a "freak operation," may not be frequently justifiable, venesection still has a place in the rational treatment of heart disease. In the presence of cyanosis venesection is certainly indicated, and the writer has practised it with benefit under these circumstances. Venesection, like cardiolysis, may be a necessary preliminary to the effective use of that agent, indispensable to the cardiologist for action upon the passive endocardial factor, namely, digitalis. The most striking results of digitalis are unquestionably observed in the control by it of the paroxysmal tachycardial irregularities of the heart's action found in association with mitral valvular disease, whether obstructive or regurgitant. The heart slows, the tumult is stilled, and quiet reigns. But it is not only in tumult with irregularity, but in tumult—that is, acceleration—with regular action, that this drug is found to still the storm. The regular failing aortic valvular heart may be succored, as well as the irregular failing mitral heart, and the failing heart which is neither aortic nor mitral, but has a sound valvular apparatus. When digitalis lays the general auriculo-ventricular storm, it lays wholly or in great measure both the auricular and ventricular tumult. What is said of digitalis applies to the whole group of which it is *facile princeps*, strophanthus alone approaching it in power and reliability.

5. Syphilis Insontium.—J. C. McWalter cites the case of a married woman, in the early thirties, the mother of four healthy children and no history of abortion, who expected to be confined the following month, and who consulted him about an ulcer at the angle of the mouth. Pathological examination revealed that the sore was teeming with *Spirochaeta pallida*. The husband, upon examination, was absolved from responsibility, no history or signs indicating syphilis. Further investigation of the woman's history showed that she had kissed a child who had an acutely virulent sore on its mouth. On consultation it was decided that salvarsan treatment might be risky, in view of the expected early confinement, and the patient was put on an ordinary course of mercury, cinchona, and iodides. The sore rapidly healed, and in four weeks she was delivered of a fine infant, which exhibited no signs of syphilis at birth, or for four weeks afterwards. In the fifth week, however, the child showed slight but unmistakable signs of congenital syphilis, which cleared up rapidly under mercurial treatment. This case proves: (1) Infection of a mother with syphilis in the eighth month of pregnancy results in infection of the child; (2) The syphilis in the child is of a milder form and develops later than ordinary congenital syphilis; (3) Infection of the mother with syphilis in the later months of pregnancy may have no deleterious effect on her confinmeent; (4) There are some cases of syphilis insontium capable of the most rigid proof.

1. Sciatica from an Orthopædic Standpoint.—J. Appleton Nutter, after recounting very briefly some of the views regarding the origin of sciatica, and reporting four cases traceable to remediable orthopedic conditions, such as faulty posture, flat feet, arthritis deformans of the spine, cites other causes of the disease. Lesions of the hip-joint (among which arthritis deformans is the most commonly found); new growths; tuberculosis; injury of the bones of the lower spine

or pelvis; multiple sarcomatosis with sciatica due to pressure in the pelvis; any form of pelvic disease capable of causing pressure on the sciatic nerve, to which may be added gravid uterus; psoas abscess; varicose veins inside the sheath of the nerve; syphilis, which is more likely to be present as a meningitis, as an arthritis of the lower spine, or as a periostitis, though true gummatous neuritis is possible; gonorrhea, acting commonly through the medium of an arthritis, though gonorrheal neuritis has been described; and variations in the lower spine may give rise to sciatica. In the differential diagnosis the writer warns of the pains of tabes. Sciatica is also fairly confused with hip-joint disease. It sometimes simulates the painful spasm of the peroneal muscles which so often accompanies a rigid flat foot. The pain seen in the calf of the leg which accompanies intermittent claudication has been mistaken for sciatica, as also that due to varicose veins. The treatment depends upon the cause. Tonsils, if diseased, may need removal, abscessed teeth may need extraction, a chronic prostatitis may need treatment. An arthritic spine needs fixation, a relaxed sacro-iliac joint should have efficient support, disease of the hip-joint calls for immobilization. All these measures will be found to have a marked effect upon the pain. For the affected limb absolute rest is essential, pillow fixation as a rule being found useful. For the pain, acetyl-salicylic acid is useful, as also the salicylates and drugs of the coal-tar class, such as phenacetin. Counter-irritation over the course of the nerve is valuable. The Paquelin cautery is very useful and should be used only very superficially. The application of mustard and the use of blisters may give relief. The injection of sterile water, alcohol, or weak cocaine solution into or beside the nerve is not often practised, as permanent damage may be done. Nerve stretching is no longer in favor, and properly so in the writer's view. In subacute cases baking and massage will generally be found useful. Hydrotherapy is sometimes of value, but like electricity more often gives only temporary relief. The injection of sterile water into the epidural space of the sacral canal has given relief which has lasted several hours or even longer. It is a procedure easy of accomplishment and unlikely to result in damage to the nerve.

Schweizerische medizinische Wochenschrift.

April 22, 1920, l, 17.

The Wildbolz Reaction.—Lanz refers to the reaction noted some months ago in the MEDICAL RECORD and known today as the "own urine" reaction. It is used only in the tuberculous and chiefly to distinguish the active from the latent form of the disease. The urine of the active tuberculous subject contains an antigan, it appears, and if inoculated into the patient's integument gives a reaction comparable with that produced by tuberculin. The author has tested it in nearly 100 cases. Attempts to sensibilize the patient to repeated injections met with conflicting results. The author gave the reaction a thorough try-out, and his conclusions were that negative results seem to exclude the existence of tuberculosis, although exceptions occur when active foci have a very thick capsule. Positive results show that foci exist in the body, but a given focus cannot be accused unless it be shown that no other exists in the body. The author made a special research into certain paratuberculous affections, such as Poncet's tuberculous rheumatism and chronic ankylosing spondylitis. His experience, while not conclusive, leads him to believe that in some at least of these cases there is a tuberculous etiology. This is equally true of Hodgkin's disease, which seems to be sometimes tuberculous, sometimes heredosyphilitic, and doubtless sometimes a mixture of the two, without reference to other causation.

Journal de Médecine de Bordeaux.

April 10, 1920, xcl, 7.

Acute Diffuse Epidemic Encephalomyelitis.—Creyx under this designation describes lethargic encephalitis with especial reference to the myoclonic deliriant form. As far back as 1917 Cruchet had isolated 9 clinical types although the material for analysis at the time was but 40 cases. Already the lethargic was regarded as but one of the types. Three years have now elapsed and the justice of Cruchet's analysis has been amply borne out. There was for a long time, however, a tendency to see but one form—the lethargic—and it is only by degrees that the original Cruchet conception has been rehabilitated. Netter with his vast personal experience has been slowly but surely recognizing the polymorphous character of the disease, and it would appear that at the outset the typical lethargic case must have been greatly in the ascendant. But according to Achard it is more likely that the atypical case at first escaped diagnosis altogether. Both theories are doubtless sound. The author gives a case of the myoclonic, deliriant type and his comments on diagnosis are of interest. The patient presented evidence of syphilis in a positive Wassermann and history of an abortion so that cerebral syphilis had to be excluded. This was done by the treatment test, which remained quite negative for the cerebral symptoms. Delirium tremens was closely simulated, so that had the patient been a hard drinking man instead of an abstemious woman another source of confusion would have arisen. Uremia and acidosis (diaceturia) could be excluded without trouble through uroscopic examination. There was no hemoculture practiced to exclude typhoid and other sepsis, but the thermic curve was not that of septicemia. Rabies would have been thought of had the subject been dog bitten by reasons of the spasms of the diaphragm associated with delirium. The case ended fatally, but the author was unable to obtain permission from the relatives to perform an autopsy.

Paraffinomas from Injection of Camphorated Oil.—Durand and Michon report this somewhat rare accident, the patient having received the oil during an attack of influenza. Several tumors had developed in the subcutaneous tissue of the thigh. While but three case reports are cited, Durand claims that the accident is not uncommon. Naturally the oil used in these cases is of mineral origin and the accident can be minimized by using a vegetable oil. In discussion analogous phenomena are mentioned in which presumably only vegetable products were used, as eucalyptus oil and oil mixed with creosote. In such cases, not tumors, but lesions suggestions scleroderma, have been seen. It is evident that this genus of artifacts is extensive and varied. Stigmata may be caused which persist throughout a long life.—*La Presse Médicale.*

First Case of Contagion of Oriental Boil in France.—Ravaut describes the following: A young girl who had never left France sojourned during the war in the Eastern Pyrenees. She was bitten every summer by mosquitos and two of the bites were followed by nodules—on the nose and eyelid, respectively. These lesions lasted a year and resisted all treatment. Diagnosis was impossible until a biopsy showed the Leishmania in great abundance, making the diagnosis of Oriental boil. Neosalvarsan caused an immediate recession of the lesion. The source of the parasite was doubtless some Kabyl or colonial white man brought into the vicinity by the war. Some of these people were employed in the graperies of the region at the time.—*La Presse Médicale.*

Book Reviews.

DIE GESCHLECHTSKRANKHEITEN Ihr Wesen, ihre Erkennung und Behandlung. Ein Grundriss für Studierende und Arzte. Von Prof. Dr. KARLZIELER, Vorstand der Universitäts- und Poliklinik für Haut- und Geschlechtskrankheiten in Würzburg. Mit 13 Abbildungen im Text. Leipsig: Georg Thieme, 1920.

THIS small pocket volume of 170 pages has a definite value to medical students and practitioners, since it presents venereal diseases in a concise and clear manner, setting forth in large type the axioms and postulates of the various subjects. The first fourth of the volume is given to gonorrhea and the remainder to syphilis. No new subject matter of particular importance is presented, but the author's pedagogic ability shines through in his sound advice and clear descriptions of technique.

A TEXT-BOOK OF PHYSIOLOGY FOR STUDENTS AND PRACTITIONERS OF MEDICINE. By RUSSELL BURTON-OPITZ, S.M., M.D., Ph.D., Associate Professor of Physiology, Columbia University; Professorial Lecturer in Physiology in Teachers College and the Extension Department of Columbia University. Illustrated. Philadelphia and London: W. B. Saunders Company, 1920.

THE appearance of a new work on physiology is welcome and timely; for physiology is coming into her own, and is now recognized as the keystone in the arch of medical education. The book before us is based on the author's lectures on Physiology at the College of Physicians and Surgeons in this city during the past twenty years. During this lengthy apprenticeship the contents of this work have naturally acquired proper proportions; the relative values of the different facts, and the best methods of presenting the same have also been ascertained; and, further, the author has learned (what some teachers never learn) that the student's time is limited, and that there are other professors with other subjects all claiming their full share of attention.

The first thing that strikes us on examining this volume is the careful and logical arrangement of the subject matter. The book is divided into nine parts, containing in all thirty sections and ninety-five chapters. This liberal allotment allows of chapters of quite moderate length, a decided advantage for the reader, and an absolute necessity for the student. In the next place, the author has not burdened his pages with unnecessary details concerning the minutiæ of anatomy, histology, embryology, chemistry, and physics. True, all these subjects enter into the comprehension of physiology, but they are only referred to in these pages when necessary to a proper understanding of the subject under discussion. At the same time, in a few special instances, the student's attention is directed to the physics of certain processes of the body, as for example in the chapters on the circulation, the respiration, vision, and on the production and dissipation of heat.

Laboratory work and experiments are duly described and explained, but the volume is in no sense a laboratory manual. This is an important feature, for many a physician is repelled by the excess of laboratory detail with which some of the more modern text books on physiology are overloaded. The author's long experience as a teacher has shown him the needs of medical students, and he has carefully allotted most time and space to the subjects likely to be useful to the practising physician. Hence, a feature of this book is the constant reference to the clinical aspects of physiology; the reader is shown the real relation existing between physiology on the one hand, and practice, surgery, and pathology on the other. The thoughtful student must appreciate, at an early period of his career, that without physiology there can be no scientific medicine and no rational therapeutics.

The volume is amply illustrated, and the numerous diagrams and original drawings are of real service, and often render more assistance than could be derived from more elaborate and artistic pictures. The author writes in an easy and attractive style, and this combined with the logical arrangement of his material makes the book of special value. It is needless to say that the book is up to date; the author's reputation as a physiologist and as a most successful teacher are ample guarantee for the quality of the work. Among the chapters which have specially impressed us are those on the action of the heart, the mechanics of respiration, the voice and speech, the sense organs, and the secretions in general (both external and internal). There are numerous references to the literature of the subject, so that those interested may continue their studies in the original authorities; but there is no regular bibliography.

LA TOXÉMIE TRAUMATIQUE (Shock Traumatique) dans les Blessures de Guerre. Par E. QUÉNU, Membre de l'Académie des Sciences et de l'Académie de Médecine, Professeur de Clinique Chirurgicale à la Faculté de Médecine de Paris. Paris: Librairie Félix Alcan, 1919.

QUÉNU covers the subject of shock fairly and completely. The subject is discussed under six headings, which may be translated as follows: Historical Review; Definition and Etiology; Clinical Course (*Evolution*); Pathogenesis; Critical Study of the Different Varieties of Shock; and Treatment of Shock.

In the historical review the various theories of shock that have been advanced (in France and countries allied with France during the late war) since the time of John Bell (1795) are mentioned and discussed, and there are almost innumerable bibliographical references and quotations from the work of French and Allied observers. Quénu finds that the conception of shock as due to a toxemia is of French origin. His definition of shock is as follows: "Shock is a syndrome characterized by arterial hypotension, rapidity and extreme feebleness of the pulse, lowering of the temperature, pallor of the skin, and a certain hypoesthesia; to this one may add shallowness of respiration." He finds that the war has (or, at least, should have) convinced surgeons that shock is due to something besides a reflex nervous disturbance; and he discusses all phases of the matter in a most interesting and instructive way, finally stressing the therapeutic measures which were tried out during the war.

DIE SCHWEBELARYNGOSKOPIE UND IHRE PRAKTISCHE VERWERTHUNG. Von GUSTAV KILLIAN, Direktor der laryngo-rhinologischen Klinik der Universität Berlin. Price 40 mks. Berlin and Wien: Urban und Schwarzenberg, 1920.

THIS work with 77 pages of text and 62 illustrations of which 18 are colored may be regarded as an atlas of suspension laryngoscopy. Over half of the text is devoted to a description of the apparatus and its introduction. Suspension laryngoscopy is then described and there follow, in the order named, pharyngoscopy, tracheoscopy, and bronchoscopy. The differences in technique between laryngoscopy in children and adults are then stated. A few Americans and British are mentioned in connection with the method, including Freudenthal and E. Meyer of New York, Davis, Lynch and others, but most of the authors quoted are Germans. Credit is given to Kirstein for the inauguration of the method, but his procedure had fallen into disuse when Killian took it up.

TREBALLS DE LA SOCIETAT DE BIOLOGIA. Any Size, 1918. Publicats sota la Direcció de A. PI SUÑER, member de l'Institut de Ciència. Barcelona: Institut d'Estudis Catalans, 1918.

THESE Transactions are published in the Catalonian idiom of the Spanish language. Seven sessions were held during 1918, devoted respectively to Physiology, Histology and Biology, and no less than five of these sessions were devoted to the first named science. There were in all 28 papers on Physiology, most of them very brief. Among the more pretentious of these papers is one by Pi Suñer on the chemical sensibility of the nerve endings of the pulmonary branches of the vagus, one by Telles on new types of microtome, one by Alzina y Milis on the oculocardiac reflex in psychiatry and neuropathology. A good proportion of the papers are devoted to technics—including the reactions of Lange, Scales-Carrasco (2 papers) and Boveri—in which blood studies predominate. The volume is well printed and well illustrated.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held March 18, 1920.

THE PRESIDENT, DR. GEORGE DAVID STEWART, IN THE CHAIR.

The Unconscious.—Dr. W. H. R. RIVERS of Cambridge University, England, delivered this address, in which he said, in part, that the concept of "the unconscious" in psychology was one which had aroused the liveliest differences in opinion and which had been met by bitter opposition. The opposition had come from advocates of the older introspective school of psychologists who had found it difficult to fit an unconscious region of the mind into their schemes of description and explanation. The aim of the older psychology was to furnish a rational explanation of human behavior and endeavor. As the material for such explanation they used almost exclusively the happenings in their own minds which could be directly, though really only retrospectively, observed, and made this material the basis of constructions whereby they fitted into coherent schemes the infinitely varied experience of the human mind. When their introspective method failed them, and they were driven to assume the existence of factors lying outside those accessible to introspection, they were accustomed to assume subconscious processes or to speak of psychological dispositions and tendencies, or they would even throw psychology wholly aside, bringing into their schemes of explanation factors belonging to the wholly different order of the material world, and used psysiological processes as links in the chain whereby they connected one psychological happening into another. It was noteworthy that the full recognition of the unconscious and the first comprehensive attempt to formulate a scheme of its organization and of the mechanisms by which it was brought into relation with the conscious should have come from those whose business it was to deal with the morbid aspect of the human mind. The necessity for the use of unconscious factors continually arose when dealing with the experiences of health, but the opportunities afforded by such experience were usually so fleeting and the experience itself often apparently so trivial that they failed to force the psychologists of the normal to face the situation. It was only when unconscious experience had contributed to wreck a life or produce a state with which the physician had to struggle, often for months or years, that it became impossible to push such experience aside or take any other line than that involved in the full recognition of its existence. It had needed the vast scale on which nervous and mental disorders had been produced in the war to force this recognition upon more than the few specialists to whom it had been previously confined. In making clear the sense in which the term "unconscious" was used, Dr. Rivers pointed out one sense in which it was not used in his paper. At any given moment we were only clearly conscious of the experience which was in the focus of attention. This formed only an infinitesimal proportion of the experience which was capable, by being brought into the focus of attention, of becoming conscious with an equal degree of clearness. At any given instant there was a vast body of experience which was not in the consciousness only because at that instant it was neither the object of attention nor so connected therewith as to occupy consciousness with more or less clearness at the time. Experience of this kind was not included within the "unconscious." In so far as the term "unconscious" applied to experience it would be limited to such as was not capable of being brought into the field of consciousness by any of the ordinary processes of memory or association, but could be reached under certain special conditions, such as sleep, hypnotism, free association, and certain pathological states. The kind of experience which formed the subject matter of his lecture, Dr. Rivers said, might best be illustrated by some examples. The first instance was that of a young man with an underlying condition of claustrophobia who was suffering from a war neurosis. For as long as he could remember this patient had been subject to a dread of confined spaces, so severe and producing states so painful and unendurable that he was debarred from taking part in many of the ordinary occupations of life, or could do so only at the risk of suffering and discomfort. His first memory of the dread went back to the age of six, when he slept with his elder brother in what was known in Scotland as a box bed. The bed stood in a recess with doors which could be closed. The child slept on the inner side of the bed next to the wall, and he still vividly remembered his fears and the desire to get out of bed. As he grew older he had a fear of tunnels and crowded buildings. During the war he went to France as a doctor, and was greatly disturbed by having to live and work in dugouts and would seek excuses to go to the trenches in order to escape from experiences which were to him far more trying than the dangers of the front line. As a result of the strain he broke down and came under the writer's attention. Taking a dream going back to the age of six and a memory as a starting point, the patient was led to recall other instances of that time, several of which were completely forgotten until recalled at this time. Later in thinking over a dream he recalled that when he was between three and four years of age he had visited an old rag-and-bone merchant who lived near the house his parents then occupied. The old man was in the habit of giving the boys a halfpenny when they brought him anything of value. He had been admitted through a dark, narrow passage from which he entered the house by a turning about half-way along the passage. At the end of the passage was a brown spaniel. Having received his reward the child came out to find the door shut. He was too small to open the door; the dog began to growl. The child was terrified. Later he recalled the name of the old rag-and-bone merchant. The patient's parents were still alive and from them it was learned that the old rag-and-bone man had lived in the neighborhood in such a house as the patient remembered, and that the patient had recalled his name correctly. The recovery of his long forgotten fright was followed by a remarkable improvement in his specific dread. A few days after recalling the memory he sat in the midst of a crowded picture house under conditions which for years would have given him the most serious discomfort. This was a typical example of the kind of experience the writer had in mind when he spoke of the "unconscious." This patient not only afforded conclusive evidence for the existence of experience shut off from consciousness under ordinary conditions, but his case showed that this experience, though inaccessible to consciousness directly, might yet be capable of affecting it indirectly.

The records of others, Dr. Rivers said, could never, however, carry the conviction which came from one's own experience, even though one's own experience could rarely have the dramatic and conclusive character of that he had just cited. The result of his self-analysis had convinced him of the reality of the unconscious. He was a person whose normal waking life was almost wholly free from sensory imagery, either visual, auditory, tactile or any other; but through the erperience of dreams, half-waking states, and of slight delirium in fever he was quite familiar with imagery. On looking back in life he was aware that his mental imagery was much more definite in youth and he remembered the presence at that period of fairly vivid visual imagery in connection with certain kinds of experience, especially of an emotional kind. In examining into his memories of childhood he discovered that he had a more definite knowledge of the topography of the house he left at the age of five than of any of the many houses he had lived in since. He had supposed that his imagery had faded from lack of attention and interest which would have kept it active, even if it had not promoted its development into the instrument which imagery had become in the mental life of the majority of human beings. It was only within the last year or two that he had discovered an aspect of his early experience which led him to revise this earlier opinion. This discovery was that the knowledge of the house he left when five years old was strictly limited to certain parts of it and that the rest was even more inaccessible to memory than any of the houses in which he had lived since. He recalled everything in the topography of the

ground floor and basement, but had not succeeded in penetrating the veil which separated him from all knowledge of his life in the upper story. He had failed to explain the blank by any mechanism provided by differences in effect or interest on memory. This early period of life was especially apt to afford occasions for experiences to become unconscious, but the passing of experience into the unconscious might happen at any age, and its occurrence had been brought into notice very widely by the experience of war. One of the most frequent features of the nervous disturbances of war has been the complete blotting out of the memories of certain events, the obliteration usually extending considerably beyond the event which furnished its special occasion. Although events might remain for months or years quite inaccessible to memory when approached by the ordinary channels, they might be brought to the surface by means of hypnotism or by the method of free association. The effects which could thus be ascribed, at any rate in part, to the experience of war fell into two main groups. They were, on the one hand, general changes in the personality, and changes in tastes, in likes and dislikes, preferences and prejudices, while, on the other hand, there were specific dreads or other morbid experiences of waking or sleeping life, such as nightmares, hallucinations or morbid impulses, which could be more or less directly ascribed to the activity of the unconscious experience. The writer did not call an idea unconscious if it sprung into the mind without obvious antecedents in consciousness, or when a person behaved in a manner which corresponded to something taking place in the mind of another person, but was not wholly, or perhaps not at all, determined by anything in the mind of the behaver, but in mentioning such processes he spoke of them as "unwitting."

Dr. Rivers then considered the question how these experiences to which he had referred became unconscious. Writers on the unconscious often used repression for the process, but he reserved this term for the process by which we wittingly endeavored to banish experience from consciousness. It seemed that this process of witting repression might be one means of producing suppression, that experience wittingly repressed might, at any rate under certain conditions, succeed in becoming inaccessible to the general body of consciousness. But there was little doubt that this was only one of the ways in which suppression occurred, and that more often it took place wholly without the intervention of volition, especially when it occurred as the result of some physical or mental shock. There was still much uncertainty concerning the exact mechanism by which suppression occurred, but there was reason to believe that in the majority of cases it took place without conscious effort, or unwittingly, and there was reason also to believe that suppression only followed witting repression, when conditions of some other kind favorable to suppression were present. One of the inquiries which might lead to the discovery of the nature and biological significance of the mechanism of suppression was the comparison of suppression with the ordinary process of forgetting. Suppression was only one form of forgetting, a form in which the forgetting was especially complete. Formerly psychologists were especially concerned with the process by which we remembered, but they had gradually been coming to recognize that the more important problem was to discover how and why we forgot. According to Freud, forgetting was not a passive process, dependent upon lack of interest and meaning, or varying with the intensity of the impression, but was an active process in which some of the mental content was suppressed. The suppressed mental content did not disappear because it was uninteresting or unimportant; on the contrary, it was usually of very special interest and had a very definite meaning. It was suppressed because the interest and meaning were of a kind which aroused pain or discomfort. Active forgetting was thus a protective process, one by which consciousness was protected from influences which would interfere with the harmony essential to pleasure or comfort. In the case of his own experience it was not possible to say why the memory of the upper floor had been forgotten, but he felt fairly confident that it was of an unpleasant kind and was forgotten because the memory of it interfered with his comfort and happiness. The conclusion to which one was led both by the experience of every-day life and by the analysis of pathological and semi-pathological states was that there was no difference in nature between the forgetting of the unpleasant experience of ordinary life, often quite trivial in character, and such examples of complete and lifelong suppression as those which he had chosen to illustrate the nature of the unconscious. The pathological suppression taking place in adult life seemed in most cases to be clearly involuntary and unwitting. The most complete cases of suppression did not occur in people who had tried consciously to repress painful experience, but had come about without any conscious activity on the part of the sufferer, especially as the result of shock or illness. Hypnotism furnished a striking example of the process by which experience was suppressed. By means of suggestion given in the hypnotic state any experience, pleasant or painful, which occurred during this state might be banished from the memory. When this had been done the hypnotized person was quite unable to recall the experience, and it would remain unconscious until he was again hypnotized or until the experience was recalled under some other condition in which the unconscious suppressed experience came to the surface. In this case the suppression took place quite independently of the will of the hypnotized person, but there was reason to believe that the suggestion to forget was more likely to be successful the more the forgetting was in consonance with the conscious wish of the subject. This probably gave the clue to the fact that conscious repression seemed often to lead to suppression. Still another characteristic of active forgetting and suppression was of great importance in understanding its nature. The experience which tended to be forgotten or repressed was the immediately painful. The process of active forgetting took no account of ultimate consequences, but was directed exclusively toward the avoidance of the more immediate pains and discomforts. The same seemed to be true of cases of pathological suppression. If, as he supposed, the claustrophobia of his patient was the result of the suppression of his four year old experience there could be little doubt that the sum total of unhappiness due to his dreads was far greater than that which would have resulted from the immediate memories of his terror when in the passage with the dog. The memory was suppressed because of its immediately painful character, and in following this course nature took no account of the effects of suppression which were to torment the child and the man for thirty years. The suppressions which formed so large an element in the neuroses of war were also directed to allow escape from the immediately unpleasant, regardless of the future consequences. Suppression was a process of reaction to pleasures and pains which were immediately present and took no account of the more extended experience with which it was the function of intelligence to deal.

Dr. JOSEPH BYRNE said that he had scarcely expected to discuss a problem that most of his hearers did not know he had been particularly interested in for many years. Psychological investigation more nearly concerned the profession as a whole than medical men would like to believe. In 1918, at the meeting of the American Medical Association in Chicago, he had heard another distinguished visitor from London, Sir James Mackenzie, insist on the necessity of evaluation of the psychological factor in cardiac disorders as a *sine qua non* for rational treatment. What Sir James so ably urged for the assessment of values in cardiac symptomatology, Dr. Byrne had already emphasized to the profession concerning the evaluation of the psychic element in all painful disorders. In all human ailments the psychological phase of the problems presented to the physician must not be lost sight of and in particular two things must ever be kept in mind, namely: (1) that pain was not to be regarded as a purely physical process and (2) that mental perturbation (anxiety, fear, etc.) was the twin brother of pain and might in any given case be the predominating factor in the patient's suffering. Thus, in any case in which pain was the chief complaint, upon analysis it would often appear that the patient's suffering is 90 per cent. or more of psychic origin and 10 per cent, or less of physical

origin or *vice versa*. The practical point here was that if the patient's suffering was predominantly of psychic origin physical methods of treatment were of little use and might even be contraindicated. Failure to appreciate this fact of fundamental significance was one of the chief reasons why the members of our profession in many States to-day stood in the humiliating position of equals, in the legal sense at least, competing with quacks and charlatans for public favor. Such a condition of affairs was intolerable to those familiar with the traditions of our calling. The fault, however, rested not altogether with the laity, but rather with the members of our profession, who frequently placed too much reliance upon their knowledge of objective or organic medicine and little or none upon the subjective or psychological side, whereas of the two, in any given instance, it often happened that the subjective or psychological side was the one that predominantly demanded attention. It seemed strange that it was on this human side that our laboriously trained representatives of scientific medicine should fail, while those unblessed with opportunities for scientific education along any line succeeded beyond measure. And it did no particular good to call these "practitioners" names. The answer the laity made to such vituperation was "They have helped us." Something here for teachers of orthodox medicine to think of. In concluding, Dr. Byrne laid particular emphasis upon the fact that in our daily lives the unconscious influenced us to an extent that was undreamed of by the profession. This was true of normal as well as of pathological states. In closing, Dr. Byrne thanked Dr. Rivers for his lucid exposition of a difficult subject and in particular for the benefits the general profession would unquestionably derive from his timely address.

Dr. STEWART PATON said that Dr. Rivers had given us a number of interesting problems to think about. It probably had occurred to many who had listened to the address how unfortunate it was for civilization that so much emphasis had been placed on the conscious processes to the neglect of the unconscious. Egotism and belligerent activities were to a large extent results of pride in our conscious life. A distinguished representative of Cambridge, Charles Darwin, had reminded us of our lowly origin; and it was fitting that another representative of that same university should remind us not only of the importance of the unconscious, but by his study of the history of primitive man he had recalled the fact that, instead of being just a little lower than the angels, we were, as a matter of fact, only little higher than the animals. It was unfortunate that medical men were not making the best use of their opportunities in studying the conscious and unconscious, and the general subject of human behavior. Think, for example, of what physicians might do in assisting the public in acquiring methods for the successful arbitration of social, economic, and international problems. We heard a great deal about subjects to be arbitrated, but as yet little had been said about methods of arbitration. Recently a distinguished European physician had pointed out some of the unfortunate results of physicians being so absorbed in the study of serology, bacteriology, etc., that they devoted little time to the study of man's conscious and unconscious processes. More should be done to interest medical students in the behavior of patients and to train those competent to undertake the investigation of social problems. The present opportunity of medical men to lead the way in the study of human behavior was unique in history. When we paused to consider the magnitude of the present opportunity it was discouraging to recall the fact that there were only three university psychiatric clinics in the United States, at Ann Arbor, at Baltimore, and at Boston; and these three clinics were by no means adequately equipped for carrying on research in this important field. New York, a city in which the examples of human behavior were probably more varied than in any other city in the world, did not yet possess a clinic of even moderate size. Enormous sums of money were spent in treating and caring for the insane, while but little was expended in investigating the causes of psychopathic conditions. Recently the study of the life histories of sixty-six revolutionary leaders in Germany had shown that practically all of these leaders had psychopathic characteristics. To-day radical changes in society were proposed by those who believed that they could direct intelligently the conscious processes without any special knowledge of man. On all sides it was becoming apparent that the organization of society could not be changed to advantage without considering the unconscious. Beneficial radical changes in human society could not be expected until we had more accurate information than we now possessed in regard to the foundations of temperament and character. During the period of the war physicians began to take intelligent interest in the so-called cases of shell-shock, and at one time the medical profession seemed to be aroused to the necessity of studying human behavior. Since the armistice this interest has rapidly declined and to-day the majority of physicians were only interested in studying the parts of the machine. It does not require profound knowledge nor very active imagination to realize that physicians could, if they would, become more active as leaders in the development of our civilization.

Dr. THOMAS W. SALMON said this was the first time he had told one of his dreams in public. He used sometimes to tell those dreams at the breakfast table, but since the technique of psychoanalysis had come so widely into vogue he had deemed it wise to abandon the practice. He now dreamed of a psychiatric clinic in New York. In addition to the psychiatric clinics which Dr. Paton mentioned, there was one at Ann Arbor, and plans were being formulated for others as integral parts of university hospitals in eight States. Each of these clinics was in charge of a medical director who was a full-time professor of psychiatry and received a salary which the rich city of New York had as yet been unable to pay to any clinical teacher of psychiatry. The dean of one institution said he did not propose any longer to send out deformed medical students who were trained only in the physical side of medicine and knew nothing about the psychic side. Sometime there would be a psychiatric clinic in New York. When that time came there should be in the front yard a statue of an American soldier in khaki, because it was the soldier with mental disorders produced by the war that had centered public attention on this question. No one worried much about the psychoneurotics before the war, though we had many even then, but when the war produced 10,000 psychoneurotics the need of making provision for their care awakened the interest of the public and the medical profession. We should have here, at the earliest possible moment, such a clinic where physicians could come to study these disorders, first for new light on their nature and causes and then for new measures of prevention and treatment. This dream, Dr. Salmon said, was not like most dreams, because some day it would come true. The only question was how far behind the Michigan city New York was to follow.

Dr. EDWARD D. FISHER said he would not attempt to review what Dr. Rivers had so plainly put before them. In the short time Dr. Rivers had spoken he had succeeded in giving the gist of this matter that had been before them for many years. Dr. Fisher said there were many things in Freud's theories that were untenable, but Dr. Rivers had shown what Freud had done in making plain those conditions that were on the border line of insanity—hysteria and psychoneuroses. There was one thing that had always puzzled him and that was in reference to the searching back for the original cause of these various peculiar mental states. It seemed sufficient to Freud's mind to find something in the past experiences of the individual that unconsciously influenced him afterward. If something that happened in childhood never came into the consciousness of the individual, how was it to have such an enormous influence on him as an adult? Take the little lad referred to by Dr. Rivers who had this experience and did not remember he had had it until it was brought to his mind when he was thirty years of age. How could that have such a tremendous influence on his life? He might have had fifty other experiences any one of which would have been capable of affecting him similarly. Why was it that this particular experience obsessed him? Dr. Fisher said he could relate instances in which there was no mystery. For instance, a boy was held in a dark room and thoroughly frightened; he never

forgot the experience and was always afraid of the dark, even when he was a man fifty years of age. The trouble with Freud was that he clung to the idea that the injury was a sexual trauma and usually an evil sexual trauma. The presentation this evening related nothing of that kind, nevertheless he could not make a connection between that early trauma and the subsequent phobia. Again, this boy whose case was cited was relieved when the supposed cause of his phobia was discovered, but the speaker had met with many cases in which the finding of the cause of the trauma had not removed the phobia, and in fact had not affected the phobia in any way. Dr. Fisher said he knew Dr. Rivers would prefer to have him speak just as he thought on this subject. He was aware that many cures did take place through psychoanalysis. Psychology had been defined as applied common sense, and common sense was an important factor in the study of these cases. It was a great thing that men such as Freud and Dr. Rivers had taken up this study, but he could not accept their conclusions. He could not believe that they always happened to get hold of the right mental trauma or injury to the personality received in youth.

Dr. RIVERS, in closing, apologized for having limited himself to the matter of definition and having said nothing about the very important problem of the way in which the unconscious produced its effects on character and the way in which it produced alterations in character, or failure of adaptation to conditions. Dr. Salmon, Dr. Byrne, and Dr. Paton had drawn attention to some of the corollaries of the subject that were of great importance to the whole medical profession and to the psychological side of disease, and particularly to the psychiatric clinics and other means of treating psychiatric disease. When Dr. Salmon spoke of the psychiatric clinics in the United States he felt very envious that so much had been done in this country while in England they had no psychiatric clinics. Dr. Rivers said he regarded it a great privilege, coming from a country where they had no psychiatric clinics, to be allowed to speak in this country where they were doing so much more in this line.

Stated Meeting Held April 1, 1920.

THE PRESIDENT, DR. GEORGE DAVID STEWART, IN THE CHAIR.

THE program of the evening was under the auspices of the Section on Medicine, and was furnished by the staff of the Peter Bent Brigham Hospital of Boston.

Acute Dilatation of the Heart So-Called Occurring During or Following Surgical Operations. Its Mechanism and Management.—Dr. SAMUEL A. LEVINE of Boston presented this paper, in which he characterized the expression "acute dilatation of the heart" as a medical waste basket for circulatory upsets occurring suddenly in persons known to have had heart disease, and in those who previously had not suffered from cardiac disorders. The exact nature of many of these upsets had remained obscure, and in fact reliable evidence of actual dilatation of the heart had been wanting. An opportunity had presented itself during the past few years to observe nine surgical cases which had some sort of circulatory upset or collapse during or following operations. In this study particular attention was paid to the mechanism of the heart beat and in each instance this was found to be abnormal. Of the nine cases three had paroxysms of auricular tachycardia, four suddenly went into auricular fibrillation, and the other two had paroxysmal auricular flutter. The striking fact was that every case had a high grade of auricular disturbance, and in all but two the condition was of transient nature. Graphic proof of the abnormal mechanism was obtained by taking electrocardiograms in six of the cases, and the clinical course of the other three left no doubt as to the nature of disturbance. While *x*-rays of the heart were not obtained in these cases, roentgenographic studies of similar paroxysmal rapid heart action were made of other cases in the medical wards, which failed except in very isolated instances to show any marked changes in the transverse diameter of the heart. The essayist noted three types of disturbances, auricular tachycardia, auricular flutter, and auricular fibrillation. A proper differential diagnosis of these three conditions was important because one type, paroxysmal auricular tachycardia, could generally be arrested by vagal stimulation, either by direct pressure over the carotid arteries or by ocular pressure. In the other two types this quick and dramatic method of controlling the disorder was impossible, and could not be hoped for. In these they were dependent upon proper digitalis therapy. These heart upsets might occur at any time during the administration of an anesthetic, or while the patient was still unconscious after the operation was completed. All three cases of auricular tachycardia occurred while the patient was still unconscious. The other six cases had their upsets following operation at varying times, from twenty-four hours to nine days post-operative. The attacks lasted from several minutes to several days in seven cases, and in two the abnormal rhythm remained permanent as long as their observations were made. At times the clinical condition of the patient became alarming during the attack, while others were not much disturbed. From the study of these nine patients it was impossible to predict what type of case was apt to have a cardiac upset during or following operation. In none did syphilis seem to be an etiological factor. Ether was used as the anesthetic in seven cases and novocaine as a local anesthetic in the other two. Clinical examination of the heart showed that one case had outspoken mitral stenosis and five others had slight cardiac hypertrophy without disease of the valves. Eight of the patients were over 45 years of age, and the other was a boy of 17 who gave no evidence of any organic disease whatever, except a fractured clavicle, for which he was operated. In a word there did not seem to be any constant etiological factor. In three patients of this series having paroxysmal auricular tachycardia the attack was terminated by pressure over the left or right carotid or by ocular pressure. Confusion would be apt to arise between auricular flutter with a regular ventricular rate and auricular tachycardia. The absolute arrythmia of auricular fibrillation practically ruled out any other condition. Vagal pressure never stopped an attack of flutter, although the ventricular rate was slowed temporarily. On the other hand, the rate of auricular tachycardia was rarely affected unless the attack was completely arrested. It followed, therefore, that if an abnormal regular heart rate slowed temporarily during vagal stimulation, the mechanism was not due to auricular tachycardia, but rather to flutter. In deciding whether a rapid regular rate was a normal acceleration or an abnormal tachycardia, it would be of considerable assistance to make an accurate determination of the apex rate, counting a full minute and repeating this observation in five or ten minutes. If it was an abnormal tachycardia the rate might not carry even one beat, or at the most not more than two beats, while in normal acceleration greater variations were found. Should the attack be one of auricular fibrillation or flutter, digitalis in some form was the one drug at their disposal. It might not be necessary to use it if the clinical condition of the patient was satisfactory, for the attack might be transient. Although none of these patients received large single doses of digitalis by the Eggleston method, one would expect that such a procedure or intravenous use of strophanthin might find a proper place under these circumstances. It was urged that well-defined terms which actually described the abnormal mechanism be employed when possible, rather than the vague name "acute dilatation of the heart."

Dr. THODORE B. BARRINGER said he thought Dr. Levine had done a very real service, particularly to the surgeon, in calling attention to this condition occurring in patients during or after anesthesia. There was a decided lack of knowledge of this subject, not only on the part of the surgeon, but on the part of medical men, so that Dr. Levine's paper was well worth while. He did not think these cases had always been termed acute dilatation of the heart. He had talked with a number of surgeons recently and the only circulatory disturbances during operation that they recognized were syncope and surgical shock. Dr. Barringer said he had also talked with several anesthetists, thinking they would have opportunities of seeing cases of

this sort more frequently than the internists. Dr. Bennett had told him that he found that chloroform anesthesia not infrequently caused paroxysmal tachycardia and occasionally ether would do the same. He said that before patients went into syncope with chloroform anesthesia they were apt to have very marked irregularity of the pulse, and also that he was never very much disturbed by these auricular tachycardias because they generally stopped spontaneously. Furthermore, Dr. Bennett believed that it was well to digitalize patients giving a history of palpitation or dyspnea before operation. Dr. Barringer said that the difficulty he had had in securing information about these purely cardiac conditions from the man who had most opportunity to see them was an excellent commentary on the service Dr. Levine had done in calling attention to this matter.

Glucose Tolerance Test in Chronic Vascular Hypertension.—Dr. JAMES P. O'HARE of Boston read this paper, which described the findings in 25 glucose tolerance tests, done on 23 cases of vascular hypertension, which threw an interesting light on the question of potential diabetes. The tests were arranged on a chart according to the size of the difference between the fasting blood sugar and the blood sugar two hours after the ingestion of glucose. The result was a widening band of difference which showed that these cases tended to merge into the typical diabetic reaction. The first seven cases showed fairly normal reactions, except that one showed glycosuria during the test. The next seven were only slightly abnormal, while the remaining eleven showed well-marked abnormalities. The last two cases, the one with a difference of 0.14 per cent. and a glycosuria of 4 per cent., the other with a difference of 0.22 per cent., and a glycosuria of 2 per cent., approached the typical diabetic reaction if they were not actually diabetic. Very little connection could be established between the blood pressure or the degree of arteriosclerosis and the variation in the reaction. It was known that cases of chronic vascular hypertension were potential nephritics. This chart indicated that they were potential diabetics as well. The test of time alone would tell whether they developed into true diabetics.

Dr. WARFIELD T. LONGCOPE said that the problem of vascular hypertension was so important and one so difficult to elucidate that such observations as those Dr. O'Hare had presented added valuable information to the subject and were of much importance. For some time observations had shown that a high blood pressure might be associated with diseased conditions other than those of the kidney. As an illustration it was only necessary to mention certain instances of exophthalmic goiter, in which the systolic pressure might be very high, while the diastolic pressure was very low. It had also been recognized that the large proportion of diabetics showed various degrees of hypertension. In further studies the group of cases which Dr. O'Hare presented, it would be important to determine whether the hypertension in most cases preceded the appearance of glycosuria, or whether the glycosuria was of long standing and the hypertension appeared later. There was one possibility that had to be taken into consideration, namely, that these patients suffered from either a functional or an anatomical disease of the smaller blood vessels. Early evidences of the vascular disease were temporary or permanent hypertension, while the late effects were dependent upon secondary changes that took place in the heart, kidneys, and possibly in the pancreas.

Epinephrin Hypersensitiveness in Hyperthyroidism.—Dr. J. T. WEARN of Boston made this presentation. He stated that this study came about as the result of the investigation carried out at the U. S. Base Hospital at Lakewood to ascertain the relationship of hyperthyroidism to the effort syndrome. During that study they had used the basal metabolism and at the same time the epinephrin tests. They had used the tests described by Goetsch. The patients were kept at rest in bed for one day, or certainly for several hours, before observations of the blood pressure and respiration were made. The degree of tremor, sweating, dizziness, palpitation, etc., were noted at the end of the rest period. Five cubic centimeters of epinephrin was given subcutaneously or intramuscularly, and observations were made on the blood pressure at five and ten-minute intervals for an hour and a half. Observations were recorded and a positive reaction was interpreted as increase in pulse rate, tremor, sweating, and palpitation. There were no reactions from the drug after 45 minutes. The reaction usually occurred within one-half hour. Several cases did not react. Goetsch had found a positive reaction in all cases of hyperthyroidism. There was a greater dilatation of the pupils in cases of diabetes than in those of hyperthyroidism. The severity of the reaction seemed to depend upon the severity of the hyperthyroidism. They had also taken 26 soldiers from the 34th Division who had trained fourteen months and were in excellent condition, and not one of these reacted to the drug. They next took 28 others, and of these four reacted. These men had been athletes and had increased systolic blood pressure and slightly increased pulse. In all the experiments the respiration was dependent upon the rate of increase of the pulse and blood pressure. In 17 cases of mitral stenosis three gave a positive and two a doubtful reaction. Then 21 cases of acute infection were tested; of these two cases following pneumonia reacted; three following diphtheria were positive, and one was negative; of eight cases following acute rheumatic fever four were positive and four negative. Of six cases of sore throat, three reacted and three did not. Other conditions in which they had found one or more positive reactions were syphilis, chorea, asthma, myxodema, acromegalia, diabetes, neurasthenia and dementia præcox. In each of these the basal metabolism fell within normal limits. Of 21 cases of hyperthyroidism, 15 gave positive reactions and six gave negative reactions to epinephrin. All of these were outspoken cases of hyperthyroidism. The cases giving negative reactions were all early in the course of the disease. Nine cases of hyperthyroidism were tested with epinephrin after the removal of the gland and four still gave a positive reaction. Forty-eight per cent. of the cases with irritable heart responded to the test. In view of the fact that positive reactions to epinephrin were observed in other conditions than hyperthyroidism, they felt that extreme caution should be exercised in interpreting this test.

Dr. EMIL GOETSCH said he was afraid it had been assumed by some that he had said that a positive response to epinephrin meant in all cases hyperthyroidism. He had never held that this was the case. He did believe, however, that epinephrin hypersensitiveness meant a hypersensitive nervous system, and that of all the diseases in which the sympathetic nervous system was peculiarly hypersensitive to epinephrin, hyperthyroidism was the one by far the most frequently encountered. In a study of 450 cases of thyroid disease with reference to the epinephrin hypersensitiveness before and after operation, he had found that it was very important to be able to control the preoperative diagnosis by very careful microscopic examination of the gland tissue removed at operation, in order to be certain, from the pathological point of view, that there was truly a histological change in the thyroid gland of a hyperactive character. Without the aid of the microscope one was frequently at a loss as to the final diagnosis. He felt now that hyperfunctioning thyroid tissue, whether of the usual hyperplastic character or of adenomatous nature, could be recognized not so much by the grosser features of hyperplasia and hypertrophy, but more precisely by the mitrochondrial concentration of the cytoplasm of the gland cells. In this manner he believed the diagnosis of hyperthyroidism could be placed upon an impersonal basis. There seemed to him to be a tendency to assume that if there was a normal or only slightly increased basal metabolism in a particular patient suspected of having hyperthyroidism, we could, therefore, conclude that this patient was not suffering from hyperthyroidism. He did not believe that this statement held true. Woodbury and Webb had found that in cases of adenoma of the thyroid with a definite history of hyperthyroidism the symptoms of the latter rapidly disappeared when these patients were put to rest in bed, and that at this time, also, the metabolic rate was normal. During the same so-called quiescent phase the epinephrin hypersensitiveness was still found to be present. In other words, this hypersensitiveness was found to persist even

through the quiescent phase when the patient was at rest, and when the basal metabolism was normal, and thus was a very definite aid in recognizing this type of case. If one were to base the diagnosis upon an increased metabolic rate one would miss the diagnosis in these cases in which hyperthyroid symptoms were so apt to reappear when the patient again assumed the responsibilities and cares of normal life. Dr. Woodbury was about to publish a number of cases of this kind in the *Journal of the American Medical Association* that were cases of true hyperthyroidism which were hypersensitive to epinephrin, but in whom there was a normal metabolic rate. With reference to the statement that a few cases which were clinically hyperthyroid, but gave a negative reaction to epinephrin, in the first place it was very difficult to state positively from clinical manifestations alone in the milder types that a case was truly hyperthyroid, and he believes he could safely say that in his experience he had never seen a case of true hyperthyroidism which did not react positively to epinephrin. Again, he emphasized the importance of considering very carefully the exact nature of the reaction before calling it positive or negative. The typical positive reaction was a sustained one characterized by a fairly prompt response to the drug with a preliminary rise of blood pressure and pulse above 10 and with the exhibition of symptoms and signs; then a fall with a diminution of symptoms and signs, and finally a fall of blood pressure and pulse and disappearance of symptoms, with a return to practically normal state in the course of one and one-half hours. There was danger of calling a test positive when there was a short preliminary rise with a quick return to normal. This was sometimes seen in psychoneurosis and neurasthenia, in which the sustained character of the reaction was missing. With reference to the metabolic rate as evidence of hyperthyroidism, it might be said that, as McCaskey and others had shown, there were instances of increased metabolic rate in conditions not hyperthyroid, as also cases of true hyperthyroidism in which the metabolic rate was not increased. One must, therefore, not control the epinephrin test, for example, by the findings in regard to the metabolic rate, for it was dangerous to control one test by another test, neither one of which was completely understood. In other words, each test must of itself stand upon its own merits. It had been stated that a positive epinephrin test was obtained in postinfectious cases, and it seemed to have been assumed that these were not cases of hyperthyroidism. He should like to differ with this opinion, for it seemed to be well founded that hyperthyroidism could result from acute infections, such as influenza, grippe, pneumonia, and tonsilitis. Patients recovering from these diseases frequently exhibited tachycardia, throbbing of the heart, asthenia, tremor, perspiration, and nervousness. These symptoms and signs might well be due to postinfectious hyperthyroidism, and the fact that these patients showed a positive epinephrin test was additional evidence to his mind that these patients did have a true hyperthyroidism. Another point he emphasized was that the epinephrin used for these tests should be as fresh as possible, for after a time the drug lost considerable of its potency by oxidation. He knew that in some instances of supposed negative reaction the latter was due to the use of old epinephrin. The epinephrin he was using was furnished directly from the Parke, Davis & Co. laboratories. It was difficult to determine for purposes of the test whether a person whom one was testing for metabolic rate or epinephrin hypersensitiveness was normal or not, for it was known that there were individuals who appeared normal but in whom one found an unstable nervous system, or again individuals might vary from day to day as to their thyroid state, which depended in a large measure upon their psychic reactions to their environment or to other factors. While the fact that some of the supposed normal individuals, as quoted by Dr. Wearn, reacted to epinephrin, did not, of course, necessarily mean that they were hyperthyroid, yet on the other hand it was not shown, he believed, that they were not possibly mildly hyperthyroid even though the clinical manifestations of such a condition were not clear. He knew that in individuals with true thyroid disease, such as adenoma, and with a typical history of periods of hyperthyroidism might have quiescent phases. In other words, he thought we must concede that there were conditions of hyperthyroidism which were not possible of certain diagnosis after the ordinary clinical examination. In brief, the epinephrin test when positive meant that the individual had a sympathetic nervous system, hypersensitive to the action of this drug and, furthermore, we all knew that of all the diseases of which this was true hyperthyroidism was the one condition which was by all odds the most frequently found. On the other hand, a negative reaction was of great value, for then one could positively exclude hyperthyroidism. The occasional case with a positive epinephrin reaction which was not hyperthyroidism could be excluded, he thought, by a careful history and physical examination, and, furthermore, by failure of most of the ordinary medical and hygienic measures. The fact that a very definite improvement, if not almost a cure, had followed thyroid resection in individuals who had undergone every other form of treatment for long periods of time without relief, in whom no other pathological basis, such as tuberculosis was found, but who gave a positive reaction to epinephrin, and in whom what he called "diffuse adenomatosis" of the thyroid gland was found, remained to be explained.

A Study of the Correlation of the Basal Metabolism and the Pulse Rate in Patients with Exophthalmic Goiter.—Dr. CYRUS C. STURGIS and Dr. EDNA H. TOMPKINS of Boston presented this paper, in which they stated that while a study of the basal metabolism was probably the most accurate method that could be used in the diagnosis and in following the course of patients with exophthalmic goiter, its exact value was not known, and as it was a somewhat complicated procedure it was not available in many patients with the disease. Certain symptoms and signs of the disease, such as tachycardia, loss of weight, warmth of the skin, and sweating, were directly referable to the increased heat production, and hence they were indirectly a measure of the presence or absence of increased metabolism. Of these signs the simplest and easiest to determine was the pulse rate, and hence a series of patients with exophthalmic goiter and increased metabolism had been studied in order to ascertain the precise relation of the pulse rate to the increased heat production and also to determine the value of the pulse rate as an indication of the presence or absence of hyperthyroidism, and as a guide to the overactivity of the thyroid gland.

In a total of 104 individuals with a normal basal metabolism, only five had a resting pulse over 90 per minute. A total of 496 basal metabolism determinations on 99 patients with exophthalmic goiter from the Peter Bent Brigham Hospital and 55 patients as reported by Means and Aub had been studied. In 426 instances the basal metabolism was elevated plus 15 per cent. or greater, and the resting pulse rate was 90 per minute, or more in 84 per cent. of these. In 70 instances when the basal metabolism had fallen below plus 15 per cent. there was a simultaneous fall in the pulse rate below 90 in 78 per cent. Probably the most accurate interrelation between the pulse rate and the amount of heat production was to be found during the course of the disease in any one patient. In a series of 52 patients with exophthalmic goiter, in whom two or more metabolism observations had been made, changes in the pulse rate gave an accurate idea of those in the heat production in 85 per cent. It was hardly to be expected that a given heart rate would always correspond to the same elevation of metabolism in different persons because of the variations of normal pulse rate in different individuals. In spite of this, however, when a considerable number of observations were considered, there was a suggestive interrelation between pulse rate and metabolism. There were, however, a good many discrepancies in which the metabolism was greatly elevated and the pulse rate relatively low. Patients with auricular fibrillation could account for the slow pulse rate associated with the high metabolism in a number of cases. In other instances the slow pulse might be accounted for by the fact that when these patients had a normal metabolism their pulse rate was unusually slow.

Dr. EUGENE F. DUBOIS said that Dr. Sturgis had

made an exceedingly careful analysis of his cases, and had drawn very conservative conclusions. He had called attention to the fact that the pulse rate was one of the most important guides in hyperthroidism, at a time when we were finding out that a good many of the so-called classical signs were not dependable. Dr. Sturgis was wise in emphasizing the fact that one might be misled by placing too much reliance in the level of the pulse rate alone in different individuals. The correlation between changes in pulse rate and basal metabolism in any one individual, however, seemed to be a valuable method of controlling treatment. There was probably a causal relationship between pulse rate and basal metabolism, because the increased demand on the oxygen consumption in hyperthyroidism was similar to the demand made by exercise. Since this increased oxidation was going on night and day, it was not surprising that the heart responded by increased rate. He was sure they were all greatly indebted to Dr. Sturgis for the laborious study of this important correlation in a large number of cases.

Clinical Experience with a Dried Aqueous Extract of Digitalis.—Dr. HOWARD F. WEST of Boston read this paper. He described the preparation of a dried aqueous extract of digitalis, in which the active principles of digitalis were in more concentrated form than they occurred in the leaf, and which was made to conform to the U. S. P. standard by mixing with lactose. A freshly prepared infusion was evaporated to dryness. This gave a fine brown powder which had maintained its activity for a year. Each lot was assayed and mixed with equal parts of anhydrous sodium sulphate, which aided in protecting the powder from moisture. It was put up in capsules containing 5.5 frog units each. The digitalis was grown in Virginia and Oregon. This preparation had been used in a considerable number of cases in the Peter Bent Brigham Hospital with uniformly satisfactory results. It was found that 39 mg. of standard leaf per kilo body weight, discounting edema, was the average physiological dose. When given rapidly, largely as single doses, to patients with auricular fibrillation, an initial effect as judged by the slowing of the heart rate was noted in from three to six hours—a complete effect in from twelve to twenty-four hours. Marked diuresis was frequently seen after large doses. When used in patients with regular rhythm who had obvious symptoms of heart failure the effects were quite as satisfactory as in those with auricular fibrillation. After large single doses they showed rapid clinical improvement, and the vital capacity of the lungs showed prompt and striking increases, amounting to as much as 15 to 20 per cent. in twenty-four hours. The vital capacity offered a valuable measure of improvement, and in patients with regular hearts was the best graphic indication of the therapeutic effect of the drug, since there was usually much less change of the heart rate than in patients with auricular fibrillation. The physiological dose was found to be practically identical with that found by Eggleston, that was, 0.145 cat units per pound body weight when the patient had become free of edema. Careful observations were made showing the effect of this preparation on pulse rate, urine output, weight, and vital capacity.

Dr. B. S. OPPENHEIMER recalled that Sir James Mackenzie had stated at the 1918 meeting of the American Medical Association that all the English preparations of digitalis which he had ever used had shown some activity. He thought this was true also for all American preparations of digitalis. The modern clinician was no longer satisfied with this, however; he required of the pharmacologist a preparation which was standardized, remained potent, and was absorbed. Dr. West's dried aqueous extract had met the requirements. Professor Hatcher of Cornell had supplied the speaker with a standardized tincture prepared from the chloroform soluble extract of digitalis which was quickly absorbed and prolonged in its action. This had been administered according to the Eggleston method in divided doses at six hour intervals. The results with it had been very satisfactory. He had not as yet ventured to use this tincture intravenously. There was still a demand at the hospitals for preparations for intravenous use; over two hundred doses of digitalis were administered intravenously each month at Mt. Sinai Hospital. Personally he used cuabaine intravenously, but it was rather generally agreed that the indiscriminate use of strophanthin without careful regard to dose and previous digitalization, would lead to fatalities. In closing, Dr. Oppenheimer congratulated Dr. West on his use of the vital capacity as a measure of the patient's improvement under digitalis. Dr. West had demonstrated a marked improvement not only in patients with auricular fibrillation, but in those with regular pulse.

Dr. WEARN, in closing the discussion, said there had been an objection to the diagnosis of hyperthyroidism by means of the basal metabolism. They did not make the diagnosis of hyperthyroidism on the basis of basal metabolism, but in five cases of hyperthyroidism that showed no reaction to epinephrin the diagnosis was made on the clinical signs and symptoms and the basal metabolism. The post-infection cases were probably cases of hyperthyroidism; they showed tremor tachycardia, nervousness and restlessness, which after rest disappeared completely. When the pulse rate dropped below 60 all other symptoms, including tremor, disappeared; these patients had not lost in weight and did well on treatment directed by the hyperthyroid condition. In their work they had used Park Davis adrenalin tablets.

Dr. WEST, in closing, said that with care strophanthin administered by mouth in one-half grain doses and large single doses of digitalis had given results quite as satisfactory as though intravenous methods had been used.

Stated Meeting, Held May 6, 1920.

THE PRESIDENT, DR. GEORGE DAVID STEWART, IN THE CHAIR.

THIS meeting was held in memory of the late Dr. Abraham Jacobi.

Dr. GEORGE DAVID STEWART, opening the meeting, said that when Dr. Jacobi was taken from us last summer the New York Academy of Medicine was in vacation. It did what it could to honor him at that time, but many members were out of town and could not offer their tribute and there were also many laymen who wished to join them in paying tribute to Dr. Jacobi. Dr. Sondern had looked into the matter and found that there was a feeling among the members of the Academy and among their lay friends that a meeting should be held in honor of Dr. Jacobi. Then it happened that the Stated Meeting of the Academy of May 6 fell on the anniversary of Dr. Jacobi's birth. He was born ninety years ago to-day. There was still another circumstance that added to the fitness of holding this meeting, that was that his daughter, Mrs. McAneny, wished to present the bas-relief, a gift to Dr. Jacobi from the Medical Society of the State of New York, to the New York Academy of Medicine, so it was decided to hold this meeting.

Presentation to the New York Academy of Medicine of a Bas-Relief of Dr. Jacobi.—Hon. GEORGE McAneny made this presentation. He said that this day, Dr. Jacobi's ninetieth birthday, recalled irresistibly, not only to the minds of those who had known him in his home but to those who knew him publicly and privately, another occasion when they had met to celebrate his deeds, his actions, and his many noble and lovable qualities. He was recalling the night, twenty years ago, when having reached the scriptural three score and ten years, and when the thought was perhaps in the minds of those who did not know him so well as those who knew him at home that perhaps he might take a less active part in life than he had done hitherto, a great dinner was given in his honor. Those who knew him well would never forget that occasion and the things that were said of him at that time. The wish was expressed that he was not through with active life and that he would continue to do even greater things than he had done. This wish was granted.

The Bas-Relief which was here was presented to Dr. Jacobi by the Medical Society of the State of New York. It was most fitting that it should be returned to the custody of the New York Academy of Medicine,

not only because of its origin but because in the ten years it was his it had had a treasured place in his study, and he believed in it. He always admired it and wanted others to admire it. Bringing it back to the Academy of Medicine was fulfilling Dr. Jacobi's own wish. The members of his family gave it in his name. His love for the Academy was a part of himself as was his love for medicine. His love for the Academy as an institution, Mr. McAneny said, surpassed anything of that sort he had ever seen. As the years crept on a few signs of advancing age began to leave their mark, but no matter what the state of the weather or his own state of body or mind, Dr. Jacobi never permitted any of these things to keep him away from the meetings of the Academy. He not only attended the meetings regularly, but his voice was raised when he thought it worth while, always in a kindly way. If at times the expression of his frank judgment might have seemed severe, it was because he believed that what he said was for the welfare of the Academy and of the profession of medicine. Above all other qualities his kindliness stood out. Those who knew him more intimately felt this more keenly than those who only saw his work out of doors. Most touching was his love for little children, and thousands of them rose up to call him blessed. To them he gave a service and a devotion that would never be forgotten by those who saw it. He felt that it was pardonable on his part to speak a little more intimately of his part of Dr. Jacobi's nature, inasmuch as those who were to follow would speak rather of his public work. He recalled that at Lake George, three days before he died, a little child was brought to him sick unto death. Dr. Jacobi, at that time, was not ill; he simply felt tired, his life over. This was typical of him—when this child was brought to him he spent an hour of his time with it, entirely forgetful of himself. The child was taken away and lived. It was not fitting to say that Dr. Jacobi died in harness, for that was entirely too rough an expression for the service of such a nature as his. For more than half a century he had made his summer home at Lake George. He was one of those wise men who set apart a portion of the year for recreation and building up. At Lake George he had his woods and water and miles of paths bearing names he had given them. He piloted his own launch on the lake, and until the last year of his life was his own engineer, refusing to accept assistance in the care and management of his boat. His love for the forest, perhaps a part of his German nature, his love for the woods and for the lakes was a very part of himself.

Mr. McAneny then read the poem to Dr. Jacobi written by Wier Mitchell and read at the dinner twenty years ago. In closing he said: "Here he served, here he was brought when he was dead. It is most fitting that he should express through this bronze reminder his continued presence with you, for his spirit must go with you in your work."

Acceptance of the Gift on Behalf of the New York Academy of Medicine.—Dr. GEORGE DAVID STEWART, in responding to Mr. McAneny, said Dr. Jacobi joined the New York Academy of Medicine in 1857, ten years after it was founded, and continued an active member until 1919. He was, therefore, connected with the institution for over sixty years, and thus a member for more years than Pitt or Fox, Nelson, or Hamilton were permitted to live, and for almost twice the span given to Byron or Burns. During all that time his punctuality and regularity in attendance were a constant reproach to less resolute spirits. But Dr. Jacobi did much more than attend the Academy during his life; he gave freely of his resources, influenced others to give largely, and in his last will and testament did not forget the institution, leaving a generous donation of money and books. In 1889, he had set a goal of One Hundred Thousand Dollars as Library Fund, and lived to see this far surpassed. Dr. Oliver Wendell Holmes, in a letter of regret that he could not be present at the laying of the cornerstone of this building in 1889, said, "The Medical Profession will always have to fight against the claims of the wrongheaded and too often dishonest individuals and *schools*, as they call themselves. A fraction of the community will always run after false prophets. There are a certain number of squinting brains as there are of squinting eyes in every thousand of the population." It always falls to the Doctor to protect the public against these astigmatics." When legislation is sought that will grant privileges to these *schools* or individuals, ignorant, undeserving, often a menace to progressive and preventive medicine, no other profession or social group will undertake the thankless task of the opposition, but most other social groups are willing to criticize the doctors who oppose, accusing them of selfishness. Dr. Jacobi was vigorous in the support of everything that he believed would forward the science of medicine, fearless in opposition to every agent, no matter how strongly entrenched, that he feared would work harm, but the Academy was to him a shrine, to which he could bring no differences other than those of his science and art. Like Lydgate, he carried "the conviction that the medical profession as it might be was the finest in the world, presenting the most perfect interchange between science and art, offering the most direct alliance between intellectual conquest and social good." Further, like Lydgate, "he resolved to reject the decorations and other humbugs of medicine and to be the possessor of genuine qualifications." As the home of this quality of Medicine, he strove to keep the Academy a thing apart. Dr. Stewart recalled that a great American had said that twenty per cent. of wisdom consisted in being wise at the right time. Dr. Jacobi was wise in his day and generation. He was never led away by unscientific gods; never misled by pseudo-science, no matter how brilliant the phrasing. To reverse Dr. Thomas Browne, his ears were opener to logic than rhetoric. In the roll of victories inscribed on the banners, the forced marches, the muddy bivouacs, the reeking trench and the driving in of the outposts were forgotten. The victories of peace rarely went down in history. However, there were many who would rather be remembered by a sonnet than a victory; who would rather build fine phrases than a St. Paul's; who would rather give a cup of cold water to a little one than to rule a province. And while it was true that the doctor, who had discovered a new drug to lessen suffering, or a new germ to conquer, was forgotten or remembered only by the few, while he did not reach the Hall of Fame, still he often lived in the hearts of his patients as a special Providence. In closing, Dr. Stewart said: "And so, Sir, we accept this Bas-Relief of Dr. Jacobi with sincerest thanks. It will serve as the symbol and suggestion that we may draw from the walls of memory, tokens of our patron and friend. Though made of enduring bronze, it is not nearly so imperishable as the spiritual legacies which he has left us and which will go on and on, for they are of the very essence of immortality."

The Life and Influence of Dr. Abraham Jacobi on His Times.—Dr. GEORGE E. VINCENT, President of the Rockefeller Foundation, delivered this address. He said, in part, that it was interesting to speculate about what might have been the outcome if the German Revolution of 1848 had been successful. Might a democratized Fatherland have followed a different course? Would the wars of 1870 and 1914 have been avoided? Who could say? This much was certain: the "forty-eighters" brought to their adopted country substantial contributions. Of this group Abraham Jacobi was a distinguished member. His life and work enriched American science, medical teaching, public health, civic organizations, and social idealism. Dr. Jacobi's early passion for democracy made him deeply appreciate the freedom of his new home. His scientific training fitted him for service of a much needed kind. He was in a sense a product of social influences but it was also true that his imagination, creative ability, courage and loyalty enabled him to influence his time in fundamental and permanent ways. He was a force in interpreting and modifying his environment. He grasped and furthered the essential features of modern medicine. He warmly advocated medical research; insisted upon the indispensable nature of laboratory methods; recognized the value of experience gained by the practitioner; and urged the necessity for the closest cooperation between laboratory and clinic. He might be said to have founded in the United States the subject of children's diseases as a division of scientific medicine. The fundamental things in medical edu-

cation were clearly recognized and intelligently supported by Dr. Jacobi. He worked earnestly for more thorough preliminary training for medical students; emphasized the need for adequate endowment and proper equipment for medical schools; suggested the closing of weak institutions and the consolidation of separate schools in a given city into one large, well-equipped and strongly manned teaching center; insisted that medical schools must control hospitals for teaching and research; urged the necessity of establishing diagnostic laboratories in school hospitals; made a special point of bedside teaching and student participation in care of patients; and demanded a general training as the proper basis for specialization. He was one of the first to declare that modern medicine aimed more and more at the prevention rather than the cure of disease. Public Health from the first made strong appeal to Dr. Jacobi's intelligence and sympathy. He looked at the health of the people as a national asset. The preservation and improvement of infant and child life were his chief interest. It was his conviction that the State had a responsibility for public health. He worked energetically for health legislation. He saw that in a democracy public opinion must be educated. He was an early advocate of campaigns of instruction in hygiene through the schools, by public lectures, popular literature and newspaper articles. He thought that every large journal should have a medical man on its staff. In the medical profession Dr. Jacobi saw the leaders of preventive medicine and the future administrators of public health organizations. Dr. Jacobi recognized and loyally discharged his duties as a citizen. His early experiences in the Rhineland revolution had given him a vivid sense of social obligation. He gave himself freely to good causes. At legislative hearings his voice was heard pleading for advances in social legislation, for protection of women and children, for higher standards in medical education. His interests were broad enough to include municipal government and civil service reform. Courage was never lacking and personal interest was always subordinated to general welfare. High ideals were exemplified in Dr. Jacobi's life and eloquently proclaimed by his tongue and his pen. Professional aims were exalted. Medicine to him was a high calling, a noble profession, not a business. He urged the cultivation of science as a lofty aim. To him service to others was a satisfying experience. He proposed the motto "Ich dien" as befitting the medical profession. Dr. Jacobi was modest and humorous. He lost himself in the causes he promoted. His sense of humor saved him from an egocentric theory of the cosmos. Virtues will abstract qualities which had been generalized from countless persons in the course of centuries. These detached elements of character could have no warmth or vividness until they were translated into concrete, vitalizing personality. Dr. Jacobi incarnated the scientific spirit, love of his fellows, unflagging devotion to his work, a firm conviction of its value, a clear vision of its larger possibilities, a deep sense of social comradeship and obligation. The memory of his fine, loyal, winning personality would live on and inspire the profession and the public which he served and led so wisely and to such good purpose.

Parasites of Venezuela Rats.—Gonsalez publishes an interesting original study of this subject in the *Anales de la Direccion de Sanidad Nacional* for July-September, 1919, i, 3. In the rats of Caraccas the author in 1918 discovered the spirochete of spirochetosis icterohemorrhagica, although the disease itself has not yet appeared in man. The animal in question was the so-called gray rat or *Mus decumanus*. No other pathogenic microorganism is mentioned, but a worm known as the *Acanthocephalus* was found in the rat's intestine. The fly known as the *Periplaneta americana* or some other acts as intermediate host in the distribution of the parasite. The worms appear to be related to the cestodes and are not known to be parasitic to man. A third parasite found, also a worm and belonging to the Nematodes, is the *Tricocephalus hepaticus*, which is not mentioned as attacking man. Both these worms or congeners are common among rats everywhere.

Therapeutic Hints.

Arthritis Deformans.—William H. Spencer has noted definite improvement in all cases of arthritis deformans treated by the administration of yeast. The distressing condition of the joints and periarticular structures termed arthritis deformans, and known to the laity as "rheumatism," is now generally considered a result of focal infection. The older hypotheses of nervous and metabolic origin have failed in substantiation, while many are the reports of improvements following the clearing up of some chronic infective process. The teeth, tonsils, nasal accessory sinuses, ear, appendix, gall-bladder, and intestine have individually been incriminated. There may be more than one focus of infection, so that careful study should be made of each case before conclusions are drawn and promises made.

Spencer cites a case in which, after three months of yeast treatment (one yeast cake thrice daily after meals) with active and passive motion of the joints, the patient was able to walk without crutch or cane, the ankle and knee joints recovered, the motion of the right hip-joint became excellent, the wrists became straighter and more mobile, though the right elbow remained unchanged, and the heart returned almost to normal size, while of the murmurs there remained only a systolic roughening at the apex. From an invalid the patient, a boy of seventeen, became a self-supporting member of society. In spite of the tonsillar disease very apparent in this case the real focus of infection was in the intestinal tract, and improvement in all probability resulted from the influence of the yeast on the intestinal bacterial flora. In three other milder cases of arthritis deformans, in older patients, definite improvement in the joint conditions and a lessening of pain on motion was noted under yeast therapy.—*Therapeutic Gazette.*

Acute Follicular Tonsillitis.—The Indian observer, Phanibhusan Mukerji, has found that great benefit is derived by giving pot. chlorate, grs. 5, tinct. ferri perchlor., m. 5, tinct. aconite, m. 1, tinct. belladonnæ m. 5, spirit chloroform m. 10, in water oz. 1, internally, every two, three or four hours, according to the urgency of the case, in cases of acute follicular tonsillitis. Inhalations of steam medicated with compound tincture of benzoin, chloroform, rectified spirit, and oil of eucalyptus with local applications of tincture of ferric chloride in glycerin, must not be omitted. — *Indian Medical Record.*

Tincture of Cockroach for Asthma. — Phanibhusan Mukerji states that tinct. of blatta orentalis (cockroach) in 5 to 15 minim doses can be used successfully as a substitute for lobeliæ etherea to control paroxysms of bronchial asthma. To prepare the tincture, place 4 cockroaches in an ounce of rectified spirit, keep them for a week and strain. —*Indian Medical Record.*

Ulcers of the Cornea. — According to Phanibhusan Mukerji, iodine lotion (iodine 2.4 grs., pot. iodide 2 grs., water 1 oz.) cures ulcers of the cornea when they are of recent origin and do not involve the cornea to any depth.—*Indian Medical Record.*

SOME PHASES OF BLOOD CHEMISTRY OF PRACTICAL USE TO THE PRACTITIONER.

BY HENRY A. HIGLEY, M.D.,
BROOKLYN, N. Y.
AND
CYRUS W. FIELD, M.D.,
NEW YORK (MANHATTAN)

THE value of blood chemistry to the practitioner depends upon the extent to which it can be accurately utilized for the benefit of his patients. A large amount of work has been done in this field and much detailed information obtained. We feel that within the scope of such information certain practical facts stand out. It is in an endeavor to crystallize in some manner their meaning that the present communicaion is offered. That which follows is based on over four thousand concordant examinations of the blood and urine by us during the past five years.

At the outset we wish to be very definite in regard to a certain point, viz., that these methods have their greatest value in early cases and not to such a great degree in those later types which are more commonly found in hospital wards. In other words, they are more directly applicable to the type of patients seen by the physician in his private practice who come to him before any severe damage has been done. On the other hand, those applying for treatment at hospitals and dispensaries belong to the less well-to-do classes and cannot afford to consult a physician until they are nearly or completely incapacitated for work. It is important that this point be borne in mind in reading that which follows, as we believe a very sharp line of demarcation occurs between these two classes of patients.

From a number of points which might have been chosen for consideration, we wish to present three. These have been taken because they seem to us to be firmly established and also are fundamental and form the starting point from which we think all correct interpretations must proceed. They are as follows:

1. So far as the study of nephritis is concerned, coincident blood and urine analyses, and therefore the coefficients, must be regarded as giving a knowledge of the renal function and not that of an anatomical lesion in the kidneys.

2. An accurate knowledge of the renal function for any given substance is given by means of the so-called renal coefficient for that substance, and cannot be known from a separate examination of either blood or urine.

3. Altered renal functions occur in two forms: First, increased or hyperfunction, and second, decreased or hypofunction.

Renal Coefficients: Coefficient (*con*, together; *efficere*, to produce) is a figure indicating the degree of physical or chemical alteration characteristic of a given substance under stated conditions. This is the definition of coefficient, and it is given here because we have encountered a great deal of misunderstanding as to the nature of the term.

We do not intend to go into a minute description of renal coefficients, but refer anyone interested to the original papers of Ambard,[1] McLean,[2] and Van Slyke.[3] Ambard was the first to introduce a mathematical expression purporting to represent the efficiency of the kidney in regard to urea and sodium chloride. McLean modified his urea formula so that it expressed the result in terms per cent. Van Slyke has recently studied the formula as related to urea and has brought forward a modification which is simpler and, in our experience, more accurate than Ambard's original or McLean's modification. Van Slyke's formula changes the coefficients in about 2 per cent of the cases, some of them becoming pathological and others normal, and these changes of the coefficients would seem to agree more exactly with the clinical condition. We have applied Van Slyke's formula to creatinine, uric acid, and sugar, and believe that it very accurately represents the functions of the kidney for these substances at the time and under the conditions that the examination is made. For chlorides we have used Ambard's original formula, which is remarkably constant.

Van Slyke's formula is $\frac{D}{Bl \times \sqrt{Wt} \times V}$. In this formula D represents the daily output in the urine of the substance in grams. This is calculated from the amount excreted in the examination period, which may last from one hour to two hours, and this is multiplied by either 24 or 12, as the fraction of time may be. Bl is the amount of the same substance expressed in grams per liter, as it occurs in the blood or plasma. Wt is the weight of the patient as expressed in kilograms. This should be the normal weight, exclusive of that gained by obesity or edema, or that lost by inanition. V is the volume of urine as calculated for the twenty-four-hour period from the one or two-hour period used, expressed in liters. A short period is obviously necessary, as the changing relations due to intake in the actual twenty-four hours would be

so large that it would be impossible to calculate a coefficient, so a fraction of the twenty-four hours is taken, and is multiplied by its denominator, so that the figure represents the twenty-four hour output if no change had taken place due to the intake or outgo. The factors used are all variable within certain limits, but, as Van Slyke has shown, they are remarkably constant within these limits.

In the case of urea, the normal coefficient ranges from 4.5 to 10.5. We have found that the coefficient for creatinine ranges from 6 to 15; for uric acid from 2 to 5; for sugar from 0.5 to 2. In the case of the sugar coefficient, we have multiplied the result of Van Slyke's formula by 10, so that it may be in more accord with the values of the other coefficients. In other words, these coefficients are the mathematical expression of the ability of the kidney to excrete amounts of the substances in comparison with the amount of the same substances in the blood or plasma at the time of examination (chlorides, urea, uric acid, creatinine, and sugar). They are influenced to a slight extent by the weight of the patient, to a moderate extent by the volume output, and to a most marked extent by the daily output and the amount in the blood or plasma.

The point we desire to emphasize in this paper is that by the use of these coefficients the functions of the kidney are measured accurately, and this finding can be compared later with the same degree of accuracy that one compares the blood pressure readings as observed on a manometer. We will show that it is impossible to determine the functional capacity of the kidney from a mere examination of the blood alone. We will also show that a kidney may have a lowered function for chlorides and still normal functions for the other substances. Again, there are patients who have lowered functions for uric acid only; still others for sugar; others for creatinine; and also others with only the urea function involved; or else we may have

We do not wish to be understood as claiming that the amount of the substance in the blood gives no information as to the renal function, for, as we have stated, in hospital cases which are far advanced or where there is a marked impairment in function, the blood figures alone do give information that is of value; but, for instance, we may give as an example two of many cases that we have studied. The figures for the urea in the blood are 49 and 40 milligrams per 100 c.c., the first case having almost 20 per cent. more blood urea than the second case. However, when we calculate the daily output of urea from the output in the unit time, we find that the first case has an output of 32 grams, while the second case has only 12; and the renal coefficients for urea are found to be 7.2 and 2.8—the first normal and the second distinctly low. At the time of this examination both patients were on their normal diets, though the diet of the patient with the normal coefficient was higher in protein content than that of the second. These patients were placed on a nonprotein diet for 72 hours, and examined at the end of that period. At this time the first patient had 25 milligrams of urea per 100 c.c. of blood, while the second had 36; the daily output of urea in the first case was 18 grams, that of the second was 10; and their renal coefficients were 7.9 and 2.8, respectively, showing no change in these figures. In other words, the first patient could get rid of his urea with perfect ease, while in the second patient the ability to excrete urea was limited.

Again, we can compare two other cases, both of them on a nonprotein diet at the time of the first examination. Both these patients had a urea of 11 and 12 milligrams per 100 c.c. of blood, being practically the same; the daily output of urea as calculated from the period shows that the patient with 11 milligrams put out four times as much as the one with 12 milligrams, and that the coefficient

TABLE No. 1

Occurrence		Type	Uric Acid Blood mg. per 100 c.c.	Uric Acid Coeff.	Urea Blood mg. per 100 c.c.	Urea Coeff.	Creatinine Blood mg. per 100 c.c.	Creatinine Coeff.	Sodium Chloride Blood Threshold m.g per 100 c.c.		Sugar Blood Per cent.	Sugar Coeff.

of the patient with this high output was normal, being 6.7, while that of the other was 1.2. If the blood urea only had been used to obtain a knowledge of the patients, the physician would have been misled, as it was very low in both cases. In order to test the question raised by this examination, both these patients were placed on a protein diet for 72 hours and the examination repeated. The person with the low coefficient showed the same coefficient of 1.2 as before, while his blood urea had increased to 38 milligrams. In the patient who had a normal coefficient of 6.5, there was a difference of 0.2 between the first and second examinations, while the blood urea was increased to 24 milligrams.

There is, of course, a group of cases who show very high figures for these substances in the blood or plasma, but these are advanced cases of nephritis and the coefficient is simply an index as to the severity of the lesion. In determining the coefficient of early cases it is extremely important to observe three points: (1) That the examination should be made in the period from two to four hours after their normal meals. (2) It should be made during their normal daily work. (3) No therapeusis should have been understaken in the forty-eight hours preceding the test.

Technique.—The patient drinks two glasses of water, half an hour after this empties his bladder, and the test period then commences and it may run from one to two hours, the blood being taken at any time during this period, as we have not found that there is any change in the amount of the substances in the blood to interfere with the working out of the coefficient.

This giving of fluid is necessary, for unless the patient passes urine at a rate of at least 500 c.c. for the twenty-four hours, the coefficients will be changed because of the phenomena of dehydration, that is, the patient will appear to have a lowered function simply due to the fact that he is not secreting enough fluid to carry them off. We prefer to collect the urine between the hours of 11 and 1 or 4 and 6, obtaining the blood at the same time. A night's rest in bed will often give markedly higher coefficients than those taken during the working hours, and they are apt to be misleading. Besides the factor of rest, there is also the factor of starvation. If the damage is severe, moderate starvation shows a heightened renal function.

The priority and frequency of impairment of these functions is extremely interesting. The two earliest and most common are a lowering of the functions for chlorides and uric acid; next most frequent, that for sugar; then creatinine, and lastly urea. We are convinced that the figures given in the literature as being normal are in some cases too high and in other cases too low. It is commonly regarded that 3 milligrams of uric acid is the upper limit in the normal, but these figures are based on at least twelve hours starvation or else in so-called normal individuals working in and about the laboratories. These individuals do not indulge to any extent in rich diets, for the reason that few working for our universities and hospitals can afford more than a very simple dietary. On the other hand, individuals with a greater income indulge in more costly diets and these diets contain a much larger proportion of purins. We have repeatedly found uric acid figures up to 7 and 8 milligrams in patients who have a daily excretion of 1½ and 2 grams of the substance, and yet in the textbooks and current literature it is stated that the normal output for uric acid is between ½ and ¾ grams for the twenty-four hour period.

On the other hand, we are convinced that the greater number of cases showing more than 24 milligrams of urea per 100 c.c. have impaired renal function for urea. Creatinine in normal individuals is seldom above 1.2 per 100 c.c. In the great majority of normal individuals with normal coefficients for sugar, we find the figures for the blood below 0.1 per cent. Changes in the coefficient for sugar are extremely interesting but we will deal with this question in a future paper.

When we come to the question of chlorides, we are on debatable ground, as the chloride content of the plasma may vary very markedly. We do feel, however, (and here we are in agreement with Allen[4]) that chlorides above 0.59 per cent. may give rise to symptoms and we have also found that chlorides below 0.52 per cent. may give rise to various symptoms. Apparently individuals react to varying concentrations of chlorides in entirely different ways. However, there is no question that the greater number of hypertension cases show a high chloride figure in the plasma and in general will have an increased threshold, for, as Ambard and McLean have pointed out, there is a certain concentration in the plasma of normal individuals which, if the chloride falls below, the kidneys cease to excrete it. Ambard has shown that this normal threshold is at or about 0.562 per cent., and from our own determinations we are convinced that this is the normal point, though many people are found who have kidneys which are more permeable to chlorides than this figure would indicate. In other words, they have a lower threshold. Therefore it is a question as to whether or no we are dealing with a true hyperfunction in such cases. It does not seem to us to be remarkable that chlorides should be so often found at fault, for in the wild state animals obtain their chloride only sparingly, while a man has more than ready access to it, and many are addicted to an excessive use as may be seen from the promiscuous use of salt, condiments, sauces, etc.

True hyperfunction for all these substances is found when there is active congestion of the kidneys or where there is markedly increased basal metabolism. It is also found in early diabetics before nephritis has developed. It is found in hyperthyroidism and in the early days of an acute infectious process, except in pneumococcic pneumonia where the chlorides of the plasma drop below the threshold figure. On the other hand, hypofunction may be the result of a chronic passive congestion, poor heart action, under nourishment, anemia, and true anatomical lesions of the kidneys. (See Table II.)

In this work the laboratory man cannot possibly make the diagnosis as to the cause of the altered renal function. That must remain in the hands of the clinician and it is he who must interpret the laboratory findings and decide what is the cause of these alterations. For instance, many cases of lowered function in regard to chlorides are benefited

by a chloride free diet, as Allen has pointed out. Again, cases of lowered renal function for uric acid are nearly always benefited by being placed on a strict purin free diet. In the early stages of the true nephropathies a rest of the function undoubtedly increases the ability of the kidney to excrete these substances. On the other hand, patients with malnutrition or anemia are made distinctly worse by being placed on low diets, because their decreased functions are due to the poor general condition and they must be built up. In any given case, it is the clinician who must decide as to what is to be done and often he will have to experiment, for human animals are not all alike, there being very marked individual reactions to treatment. In the cases of markedly advanced nephritis of the chronic type with a true anatomical lesion, we have never seen a change for the better in the coefficients; they are continually on the down grade; treatment does not alter the basic condition.

In Table III repeated examinations on various patients showed the effect of treatment on changing the functions. It will be noted that in the cases of true nephritis there is no marked change in the coefficient figures, while, on the other hand, in those cases that are not clinically nephritis, the coefficients have increased, showing that the functions of the kidneys have improved. We could present reports of a large number of such cases, but space forbids it as they would be but a repetition.

Conclusions.—We have shown that by the use of coefficients an accurate measure of the functional activity of the kidney for five substances is easily ascertained; that these coefficients are of value only in the diagnosis of functional condition and early cases; that they are not an indication of a true nephritis and cannot be used by themselves to determine whether there be an anatomical lesion of the kidneys or not; that these coefficients are remarkably constant, as Ambard, McLean, Van Slyke, and numerous others have already pointed out, and that they have not been appreciated because they have been applied in the great majority of cases to hospital or dispensary patients and for the purpose of establishing a relation between them and an anatomical lesion. The functional condition due to poor general bodily tone is paralleled in the case of the heart where we may find signs of a serious lesion, though a good clinician differentiates the two conditions and can as a rule decide whether the cardiac weakness or symptoms are due to a true anatomical lesion or merely to a functional condition.

We think we have shown conclusively that their chief value is not that of establishing an anatomical diagnosis but in indicating a faulty function, and that the clinician can improve these functions by appropriate therapeusis, provided that it is only functional and not due to a destruction of the kidney parenchyma.

TABLE No. III.

	Sept. 1	6.8	.78	18.7	5.8	.87	6.4	580.	514.	Nephritis
Case 1.	Oct. 3	5.8	.8	9.4	7.2	.88	6.5	570.	502.	Nephritis
	Nov. 8	5.	.9	9.2	7.4	.84	6.9	565.	502.	Nephritis
	Oct. 2	8.4	1.9	37.2	.96	1.	6.1	645.	600.	Nephritis
Case 2.	Nov. 10	3.6	2.	35.	1.	.95	6.4	620.	584.	Nephritis
	Jan. 4	3.4	2.1	34.	1.	.93	6.4	620.	594.	Nephritis
Case 3.	Aug. 3	9.7	1.	38.	1.5	1.1	3.2	575.	513.	Anaemia
	Oct. 28	4.6	2.	26.4	3.9	1.2	5.3	580.	524.	Anaemia
Case 4.	Nov. 20	7.7	1.3	36.2	1.2	.89	3.8	645.	600.	Undernourishment
	Jan. 29	2.4	3.8	17.1	5.6	1.2	5.9	565.	535.	Undernourishment

The methods used for the determination of these substances are as follows:

For urea, the Van Slyke and Cullen method, (5) both in blood and urine.

For uric acid, the Folin (6) method as modified by Benedict.

For creatinine, the Folin (7) method.

For sugar, Benedict's (8) methods.

For chlorides, Van Slyke and Donleavy. (9)

From the foregoing, it will be seen that extremely careful and accurate work must be done if the coefficients are to have any value, as the coefficient may represent a pathological condition in the laboratory and not in the patient if the determinations be not made with the greatest accuracy. And also that to the patient it is more important to know the functional capacity of the kidney, than to think that one knows how that kidney will look at the autopsy table.

CONGENITAL AND ACQUIRED HEART CONDITIONS WHICH GIVE RISE TO SYMPTOMS; THEIR SIGNIFICANCE AND TREATMENT.*

By ORRIN S. WIGHTMAN, B.A., M.D.,

NEW YORK.

PROFESSOR OF CLINICAL MEDICINE, NEW YORK POLYCLINIC; VISITING PHYSICIAN TO POLYCLINIC AND CITY HOSPITALS; CONSULTING PHYSICIAN BAYONNE HOSPITAL.

BEFORE assuming a more general conception of diseases of the heart it might be well to observe carefully the structures which enter into the formation of the heart, particularly as applied to nerve and muscle. The development of the heart starts with the elementary tube which in its subsequent development divides and subdivides into auricle and ventricle. The primitive tube is the receptive center for nerve impressions and in the subsequent development of the heart this nerve center is practically the channel through which the heart receives its stimulation. There are two theories as to the manner in which heart tissue contracts, the Myogenic and the Neuropathic. The myogenic theory assumes that the muscle fibers have within themselves the power to generate stimulation and an independent action; the neuropathic theory requires the presence of an interlocking nerve plexus distributed throughout the cardiac tissue.

The point which concerns us this evening is that, in spite of the two schools of thought, we must be impressed with the fact that we are dealing with an organ so constructed that it seems able to generate its own impulse and at the same time accept outside stimulation in performing this function. Hearts, like individuals, have tissues which are peculiar to their inheritance. Many individuals are physically strong but have vulnerable lung tissue. Other families show degenerative kidney changes, while still others seem to have a selective weakness in their arterial system. When we speak of diseases of the heart, we cannot confine ourselves to the organ alone, but must include the arteries and veins as well. With this elaboration of the subject, we have to consider, not only heart muscle, but friable veins and arteries whose integrity is just as important as the heart itself. In families where the circulatory system is either of a low grade or is unable to stand the stress of life, we find a tendency to weakness. These types complain of poor circulation, they chill easily, they suffer from hemorrhoids, they show a venous weakness in varicose veins and phlebitis, they bruise easily showing the vessel structure is friable, and they may complain of retinal hemorrhage under slight exposure. In typhoid fever they are poor risks and very apt to develop intestinal hemorrhages, also cerebral hemorrhage is not uncommon as they advance in years.

The effect of early life on the heart is very important. We must remember that all infections which enter the system reach the blood, and, once here, pass through the heart leaving their marks. This is particularly true of such diseases as infection of the adenoids and tonsils, both of which may form pus pockets for active or subacute absorption into the circulation. More than this, the anatomical position of adenoids and tonsils is such that it is an easy matter to infect the mediastina secondarily, where glands thus infected become sources of danger for a long while to come. The particular offenders among the acute infectious diseases are scarlet fever and diphtheria; typhoid fever has also always played a part through its exhaustive duration in laying a foundation for future heart trouble. The latest addition to heart infections, namely, the influenza epidemic, has left a serious effect upon cardiac tissue. This was probably due not only to the severity of the infection, but also to the fact that the suprarenal glands were involved as well. Infection cannot enter the blood current without leaving behind destroyed serous surfaces and degenerative muscle changes which may extend to the valves of the heart. The most serious bacteria are streptococcus and staphylococcus, particularly the viridans. The typhoid bacillus and pneumococcus are frequent offenders.

In spite of all of our pathological studies it is extremely difficult to appreciate what the living heart is doing. We may study the tissue changes in the dead organ, we may find evidences of fatty degeneration, destruction of muscle fiber or valves which show marked destructive changes and incompetence; and yet this same heart in life performed its function and carried the patient along for many years. Pathological specimens are always hardened and contracted and there is no way of proving their elasticity or the ability of dead tissue to functionate; therefore we are in ignorance of the living pathology except to know the destructive tissue changes which may take place, and it makes it all the more important that we study the physical signs and clinical symptoms carefully before making any reference to the pathological findings.

Congenital heart cases are comparatively frequent. The so-called "blue baby" with the unclosed foramen ovale was shown to this Society in a wonderful selection of pathological specimens by Dr. Walsh. If the foramen ovale is faulty and either unable to close completely or leaves a leak of too large a dimension, the patient may die immediately, or if the child survives the second year of life, within a reasonable time thereafter it dies a lingering death in early adolescence. These cases are poor risks.

*Read before the West End Medical Society at the May meeting, 1920.

The next type of congenital heart is the syphilitic. Too little attention is paid to inherited syphilis in the young. We assume from the air of prosperity, and the evidence of wealth in our patients that the offspring from such people could not and should not come within the horizon of suspicion. This is a great mistake; unless the child shows unmistakable evidences of the rheumatoid group, such as tonsillitis, throat infection, chorea, etc., we should invariably have the blood examined.

Children subject to prolonged labor with trauma to the cord, to the use of anesthetics, and those which are born prematurely from 7 to 8½ months, have the most difficulty in establishing a satisfactory circulation. The field of preventive medicine should include the elimination of all predisposing elements in these cases.

Another thing of importance in the acquired heart conditions is early malnutrition. The pediatrist, if he is fortunate in establishing formulas which agree with the bottle-fed child, secures the amount of nutrition which will take care of the circulation. Experimentation in infant feeding is doubtless accountable and a contributing factor in many cases of weak hearts in children. Those children which show circulatory disturbances should be carefully managed in early life, they need rest and food, absence of excitement, and an avoidance of any of the infectious diseases. As the child grows, it may show a marked tendency for athletics. This is particularly true of the high-strung nervous child, who seems to have a boundless amount of energy and is not ordinarily fatigued. There is, without question, in this type a lack of glandular balance, but, for the purpose of our paper, we are more interested in the fact that the cardiac response is too rapid and the child will run a pulse far above what it should to maintain health. The boys at Eton, a preparatory school in England, are all put out on long runs on the road to develop endurance and strength. It seems almost Spartan in its cruelty if the child only proves its fitness to live by suffering. This is the child who, through parental pride, is allowed to assume an athletic burden which the heart cannot endure. The child at first excels owing to the ability of the heart to respond, but when the musculature of the heart is compelled to stand the endurance or fatigue of competition, valvular trouble invariably results.

After all, too much stress is laid upon heart examinations with their resultant abnormalities in sound, and too little attention is paid to the clinical study of what the heart is actually accomplishing. Of the two, the clinical study of the heart's ability to do its work is of infinitely greater importance. Under the law of economics, the insurance companies have concluded that hearts which have abnormal valvular sounds are not good risks. They have arrived at this conclusion after considering many hundreds of thousands of cases, following their histories through life and then compiling results. This is purely a mathematical computation with them and totally eliminates the personal equation. From this result, the medical fraternity is overwhelmingly impressed with valve sound murmurs, yet many people live to a good old age and never lose their heart murmur. I have in mind now a case who, at the age of 29, was warned to be very careful because he had a mitral lesion, and for thirty years this man literally walked on air for fear he would in some way injure his heart; he subsequently died of cancer of the stomach at the age of 83, never having had any recurrence of heart symptoms.

The organs supplied by the heart should first be examined for cardiac deficiency. Inasmuch as the blood promptly reaches the lungs for aeration, it is in the lungs that we first look for the evidences of stasis. You will find the bases of the lungs will show rales when there is the slightest deficiency or damming back from the mitral valve. Another organ which is prone to show enlargement is the liver; again, in lung conditions, the hacking cough with the slightly blood-stained sputum, so often mistaken for tuberculosis, could be promptly differentiated by a careful examination of the heart. The extremities show early edema, the rings become tight on the fingers, the kidneys show traces of albumin from stasis, while suffusion or exudation in the brain and mental stupor are extremely suggestive of circulatory disturbances. Dyspnea on the slightest effort, faintness, and a peculiar secondary pallor are frequently found to be cardiac symptoms. Far better to recognize the stasis and symptoms of indigestion as cardiac than to continue with digestive remedies which do the patient no good.

Some murmurs of the heart clear up under slight exertion and it is humiliating when a clinical case has been carefully examined, and the mild mitral blow easily distinguished, to find this same case practically normal when brought before an amphitheater of students. I cannot lay too much stress upon the importance of judging the heart by the work it is able to accomplish and not by the sounds. There are serious heart lesions which coincide with clinical findings. When we leave the mitral valve, we inspect the aortic area and the aortic valve which is found oftenest diseased in middle and advancing adult life. The aortitis and high blood pressure are almost synonymous and yet in these cases of aortitis, if we would cease considering the respectability of our patients and have a Wassermann test made, we would more frequently reach the correct diagnosis of syphilis, congenital or acquired. I have seen blowing murmurs over the aortic area, however, which cleared up under prolonged treatment with iron.

The irregular hearts, which compel us for a moment to dwell upon the miogenic and the neuropathic theories, are most interesting. Briefly, the medical profession have accepted the medical theories of Mackenzie, Lewis, and McLeod, relative to the muscle and nerve impulses which are necessary for the normal heart beat. The center which receives cardiac impulses is at the base of the heart, in fact, is generally accepted as the sinus node. The impulse to contract spreads uniformly from the sinoauricular node to the auricular-ventricular node and then to the ventricles where contraction starts in the papillary muscles. It is extremely important to remember the mechanism of contraction if we are to understand the arrhythmias which are very frequent in cardiac disturbance. This theory of contraction was early recognized by Mackenzie. We know that, the channel of nerve impulse being clearly established, it is easy to understand that a

weak or heavy nerve impulse would cause cardiac contraction in proportion to the amount of nerve stimulus which passes through the nodes and eventually reaches the muscle. When complete stimuli do not reach the ventricles we have missed beats. Excessive stimuli cause accentuation of the heart beat and a disarrangement of the cardiac cycle. The so-called irregular heart is one which suffers from faulty stimulation. Carried to the ultimate degree this may become heart block, or it may become bradycardia or tachycardia.

The significance of Heart Irregularities.—Medical men are in general agreement as to the relative seriousness of cardiac murmurs. The mitral valve when stenosed gives the least trouble; next comes the regurgitant mitral. The aortic when stenosed will work under effort for a long while, but, if regurgitation takes place, the last bulwark in the left heart is passed and the right side of the heart is soon involved. This means trouble as visceral stasis ensues.

The questions invariably to be determined are: How much reserve hypertrophy can be developed? Has fatty degeneration started? What is the family history relative to age and demise? What material have we to work with? If the trouble is a valvular leak with a necessary hypertrophy to restore the compensation, then how bad is the leak, and again how much reserve muscle tissue have we to draw upon?

As I stated before, when the aortic has given away and the various viscera show stasis, the only evidence of cardiac improvement must come with a restoration of function on the part of the organ affected. The stomach must digest better, the kidneys must secrete a normal amount of urine with a rational gravity, the liver dullness must abate, edema must subside, and fluid wherever present must either be withdrawn not to return or gradually disappear of its own accord. This is a proper conception of cardiac treatment. A young girl with marked anemia, slight dry cough, with blood-tinged sputum should be carefully examined for mitral stenosis with regurgitation. Congestion of the nasal mucosa in these cases often produces nosebleed. Frequent nasal hemorrhage is suspicious of mitral trouble in the absence of local causes. Again, the patient who presents a basal cardiac murmur covering the aortic valve area and following the arch of the aorta, should invariably have the blood pressure taken. High tension types will show a murmur. Low tensions with an aortic blow are suspicious of specific origin. Verify this before making a diagnosis and, if the report of the Wassermann is not satisfactory, put them on a modified specific treatment and make a diagnosis on the results of treatment. It is a common mistake to waste time over fine points in diagnosis when the suffering patient can be made comfortable by a little experimental medication.

There are a certain number of patients with arrhythmic hearts who are able to live their individual lives with bad sounding hearts but comparatively little discomfort. These are in line with the proven theory of Mackenzie that they are due to an interrupted nerve impulse in the sinoauricular or auriculoventricular nodes. A broken impulse means a poor contraction or a compensating contraction, all of which is interpreted by an irregular and uncanny pulse tracing. Do not spend too much time looking over the terrors of a pulse tracing whether it be an electrocardiogram or a plain tracing. Bear in mind that the technique in all cases plays an important part, and many variations which may appear pathological are merely due to differences in application of machinery.

I have found tracings useful when they offered a comparative test in sequence after periods of observation. On the other hand, I have been embarrassed to find two consecutive readings of the same pulse taken at the same time and sitting, which, due to slight differences in application, have given me different readings. We are never going to be able to reduce the science of medicine to any combination of mechanical tests which will replace the fundamental power of careful observation. Unless we lose sight of the tests and see what the patient is able to do for himself in the way of living we are practising near-sighted medicine.

Now as to *Treatment.*—A congenital heart which shows an open foramen ovale is of bad prognosis and is better off out of the way. Nature provides for this and the bearers of such hearts do not survive much beyond the period of adolescence.

The specific heart needs no comment beyond prompt treatment by mercury and the iodides and the use of rest, and not digitalis. Stimulating a specific heart which has not had mixed treatment first is unscientific and injurious. You are whipping a cripple.

Medicine plays a minor part in the treatment of heart disease. Our first need is to take account of stock: the age, occupation, type of work, and the future must be carefully considered. We must adjust the life of the patient to his cardiac condition. This does not mean impressing him with the fear of heart trouble for life, but rather insisting that his vocation and pleasure shall be along lines which do not produce heart strain. If it occurs in a child, the child should be excused from athletics and gymnasium; it should not be allowed to climb stairs and should be forbidden to run or unnecessarily strain itself at play. The child with a heart murmur should merely be careful and the general physical condition of the child should be carefully studied.

Do not use stimulation when the heart is already taking good care of itself. The murmur is merely a danger signal and not necessarily a deadly menace. The milder mitral disturbances are not prohibitive in child-bearing women. Study carefully how well the heart takes care of the body needs and remember that some functional murmurs disappear after the well adjusted use of iron. The child can get a large amount of iron from a carefully studied cereal selection. When it becomes necessary to use cardiac stimulation, start out with the idea of helping the heart; although the heart needs assistance there is also danger of whipping it too much unless care is used in the selection of medication.

Digitalis is the one drug universally chosen by the profession as specific in heart diseases. Much careful and scientific work has been done in trying to determine the best preparations to meet the need of the physician. Within a few years the demand for a good hypodermic preparation has resulted in

the elaboration of fat-free digitalis preparations. The result has been products offered to the profession under the name of digipuratum, digitoxin, digalen. All are efficacious where a rapid result is desired and the patient is unable to swallow. After all, we find in the standardized tincture results which cannot be questioned, and inasmuch as the digitalis is used here in its entirety, its effect on the heart can be relied upon. It is better to select one preparation of digitalis, such as the tincture, and by combining one of the digestive extracts to secure a preparation which the majority of stomachs will tolerate.

Recently the investigations of some of our experimental schools have given us to understand that the maximum effect of digitalis is not reached until the drug has been administered seventy-two hours. There is also a tendency to give massive doses with the idea of saturating the circulation as soon as possible. I fear I disagree with both of these theories. In the first place the use of digitalis, when once started, must be continued practically for life. The person once compelled to resort to digitalis is rarely able, in chronic heart disease, to discontinue its use for long intervals. If this is so, we then have our problem reduced to a very simple equation; we have about so much heart muscle left, and an equal amount of reserve force which is able to respond to stimulation. If we apply our whip very vigorously we wear out the organ that much sooner, as it is alarmingly certain that the dosage of digitalis always increases and rarely diminishes. In earlier times, it was considered to be a cumulative drug.

I do know from my own experiences that, when giving large doses of the tincture of digitalis, my cases, instead of recovering anything like a regular beat, went into collapse. If it is necessary to resort to large doses, or if we feel that digitalis takes too long to get a quick response, why not use caffeine citrate, or sparteine sulphate or caffeine-sodium-benzoate, or for that matter plain strychnine? Any one of these, if given at the proper interval, will permit the heart to hold out until the effect of digitalis is fully asserted. I believe the wisest way is to give just as little digitalis as the patient can get along with. This cannot be ascertained until the patient has been put to bed and a reasonable period of rest established. We are endeavoring to see what the patient can do for himself; first, without medication, secondly, how little medication he needs in the condition of rest to establish his circulation, and finally, what stimulation is demanded to enable him to carry out a simplified mode of useful activity. This is the rational treatment of heart disease.

Let us get away from the enthusiasm of theory in these cases and study the patients themselves, endeavoring to restore them to modified usefulness, rather than exploiting anybody's theory relative to dosage and rapid restoration of function. Bear in mind that many cardiacs outlive the physician who makes the diagnosis and arbitrarily consigns his cases to the terror of sudden death. This is a grave responsibility and each physician should think carefully before injecting into the life of his patient any further misery and discomfort.

3 West Eighty-first Street.

CONTRIBUTIONS TO THE TREATMENT OF PULMONARY TUBERCULOSIS.

By ERNST ZUEBLIN, M.D., F.A.C.P.,

CINCINNATI, OHIO.

(FROM THE CINCINNATI TUBERCULOSIS SANITARIUM.)

For the past years our endeavors were directed toward the detection of new means of treatment in this disease in which so many attempts have been made to secure better results than by the routine methods generally adopted. All colleagues by a close clinical study of the cases have reached the conclusion that with an extensive involvement not only affecting the upper lobes but also having encroached upon the apices of one or both lower lobes, very little can be expected for an arrest of the disease. A resigned pessimistic attitude is shared by most professional men.

Any new medication praised and hailed by the non-professional public as a sure cure of the ill effects of the bacillary infection is looked upon askance and for fear that our illusions may early fail to materialize. Instead of "watchful waiting" for results we are early inclined to discard any possibility of ever accomplishing anything in the line of treating the far-advanced cases of the disease. With so many clinical reports published one frequently misses the convincing proof that one or the other of the praised remedies was really the reason for the improvement.

The properly conducted university institutions, aided by a careful study of clinical and laboratory findings, can help a great deal in ascertaining the positive or negative virtues of a recommended remedy. The search for truth, particularly along therapeutic lines in which the profession and humanity have been disappointed so many times, requires extensive and fundamental study for a long period upon extensive clinical material in order to reach useful and truthful conclusions.

Requested to review in a preliminary communication my observations collected in a series of cases treated with vegetable proteins (kindly furnished me from the private laboratory of Dr. A. S. Horowitz), the data contained below may be of educational interest. As a preliminary report it is desirable to mention besides a few typical clinical cases only the salient features and impressions gained while treating the medium and far-advanced cases by the subcutaneous injections, leaving the details of physical findings, technique and changes observed in blood pressure, size and sounds of the heart, the hematological changes, the aspect of the pathological lung specimens, etc., for a later contribution. It may be stated that in the series of twenty cases the results were not uniform. This was partly due to differences in the type of cases, the doses and intervals at which the injections were given, and was also dependent to a great extent upon the cooperation given by the patient himself in the pursuance of the treatment.

Case I.—G. M., colored, age twenty-six, re-admitted to the Cincinnati Tuberculosis Sanitarium on August 17, 1918. History of active, open pulmonary tuberculosis since 1915. Physical findings on admission (August 20, 1918) active, open pulmonary tuberculosis, III, C. 22, diffuse, active involvement of all lobes with cavitation in vertebral, first interspace trunks on either side. Marked extent of moisture, diffuse involvement

of apical and horizontal trunks of both lower lobes, moderate involvement of basal trunks. Beginning involvement of right middle lobe trunk and lingual tip. Sputum positive Gaffky III. Amount of sputum, one ounce positive urochromogen reaction. Diameter of heart R. 7.5 cm., L. 7.5 cm., trans. 15.0 cm., obl. 14.3 cm., height 8.1 cm.; cardiac triangular surface 60.75 cm.^{2}; pulse 104; blood pressure, systolic 128 mms., diastolic 90 mms.; pulse pressure 38 mms.; weight on admission 126; temperature 97.4°, pulse 80, respiration 16.

Patient received the ordinary treatment consisting of rest, cough medication, and ordinary diet up to January 15, 1919. In the course of five months he had gained ten pounds.

Physical examination before treatment was started on January 2, 1919, showed a persistent involvement and active process of all trunks of both upper and lower lobes, with still existent activity throughout left base. Signs of cavitation very pronounced over first and second intercostal spaces on right and left side anteriorily over vertebral and first interspace trunks. Practically speaking, hardly any change has occurred in the physical findings during the past five months. The patient still had a positive sputum Gaffky III with mixed streptococcic infection. Was advised to have a trial treatment with the vegetable protein, proteogen.

From January 15 to May 16 he received 43 injections, beginning with 8 minims, increased gradually to 26, reduced to 14, and increased again to 20 minims. The reactions were noted as 1 or slight up to the last three, which were characterized as quite marked, the arm being quite sore. The appetite and sleep remained good throughout the course.

The patient noticed, as in similar instances, that during the next twenty-four hours following the injection the amount of sputum was decreased, which was followed by an increase in the secretion after the lapse of that period. Before, a considerable tiredness and exhaustion was noticed on the least exertion, which sensation had diminished in the course of the injection treatment. The patient, when asked whether he would prefer if the injections be discontinued, answered in the negative. Afflicted with a chronic laryngitis, during the treatment, no change in the hoarse voice could be noticed. During the treatment the patient's weight had ranged between 136½ to 133. In the space of four months, however, he was able to undertake the work in the laboratory, ranging from four to six and later eight hours, without any particular discomfort. The temperature was in general subnormal, ranging from 96.2° to 98.6°. The blood pressure range was: Systolic, 118-140 mm.; diastolic, 80-100; pulse pressure, 24-48.

The sputum findings one week after beginning the injection treatment were negative. Two weeks later a Gaffky IV could be noticed. Three months later it returned to a Gaffky II, and nine months later a negative sputum was obtained. Eleven months after beginning of treatment, or six months after cessation of the same, it became positive with Gaffky II. A complement fixation in this case was negative for syphilis as well as for different strains of tubercle bacilli when made in November, 1919.

The physical findings in this patient are particularly interesting. Five months and a half after onset of treatment, or one month after treatment had ceased, the sclerosis was particularly conspicuous on the right upper lobe, involving all upper trunks, especially vertebral and first interspace trunks, but no activity could be detected over the entire right upper and right lower lobe. Sclerotic changes also were obtained over apex of right lower lobe on the left side. Activity was slightly noticeable in the lower part anteriorly, particularly in the second interspace and horizontal trunks and lingual tip, with signs of cavitation in the left upper lobe, harsh breathing still prevailing over the left lower lobe, but no activity presented itself. On October 31, 1919, these changes were still more conspicuous, but the cavitary signs over the right upper lobe, vertebral and first interspace trunks were less conspicuous. Posteriorly, only a few crackles were noticed, besides harsh bronchial breathing and increased whispered voice. A hush breathing could be detected in right base posteriorly. The left lung also showed signs of sclerosis in first and second interspace trunks and vertebral trunks anteriorly and posteriorly. The left lower lobe, particularly the upper half, revealed fine moist rales spontaneously and after cough.

It is evident with the exception of the left lower lobe patient's condition appeared somewhat better. Activity was suggested also in the lower lobes. Weight 127 pounds, as compared with 133 pounds when treatment was discontinued, confirming such a suspicion.

Examination on January 13, 1920, one year after the treatment had been started, or eight months after discontinuation of the same, slight activity, but more sclerosis was encountered in the second and first interspaces on the right side, with sclerosis more pronounced throughout the left upper and apices of both lower lobes.

The changes in the heart findings in the size of that organ may be of interest:

Date	1/2/19	6/20/19	10/31/19	1/13/20
Right	5.5	6.8	7.8	7.8
Left	7.5	7.5	5.6	5.3
Trans.	13.0	14.3	13.4	12.8
Height	8.5	10.0	8.1	8.1
Obl.	12.5	15.6	13.7	13.7
Cardiac Triangular Surface	55.25 cm^2	58.6 cm^2	54.27 cm^2	57.60 cm^2
Heart Sounds	Accentuated tricuspid.	Accentuated first tricuspid.	id.	Indistinct deviation of heart to the right with possible dilatation more marked than ever before.

Clinically, the patient was doing better up to October 31, 1919, when, consecutive to a cold he developed sinus trouble in his nose, but he kept on working faithfully without any special complaints. On February 4 he complained of a chill with high temperature, amounting to 102.8°, pulse 112, respiration gradually increasing from 24 to 34 per minute, presenting marked cyanosis, extensive pulmonary involvement, in consequence of which the patient died, notwithstanding all efforts of keeping up his failing circulation and the marked toxemia.

The description of the pathological specimen of his lungs will be given later, as being of particular interest with regard to the extensive sclerosis and shrinking of the affected tuberculous lungs, probably in close connection related to the action of the proteogen treatment.

Although the immediate results of the proteogen therapy were favorable, it is to be regretted that the patient became a victim of an influenzal bronchopneumonia and that his heart did not have sufficient vitality to overcome the marked congestion and toxemia. This case is another illustration of the danger of secondary infections invading the lower lobes when the sclerotic upper lobes are unable to functionate properly in the efficient supply of oxygen for the body.

Among twenty of our treated cases eight are still alive. Part of them while attending faithfully to the treatment were benefited, while others who did not fully cooperate had temporary improvement, as will be discussed later. Twelve of this series of cases died, partly because their pulmonary condition was too far advanced and too active to give any favorable results.

Another illustration may be cited:

CASE II.—A. M., white, male, age thirty-three. Open, active pulmonary tuberculosis of twenty-seven months' duration. Re-admitted five times, repeated spells of pulmonary hemorrhage. Under our supervision since March 6, 1918.

Physical findings on readmission: Active, open case, involving all trunks of left upper lobe, with cavitation, signs, all trunks of right upper lobe and extensive activity over apices of both lower lobes, not excluding a broncho-pneumonic outspread into the right

middle lobe. History of repeated pulmonary hemorrhages in the past two weeks. Pulse rate 112; systolic pressure 125 mm., diastolic 90 mm.; cardiac activity 22,080 mm. pro minute. Weight 125 pounds, height 5 feet 7¾ inches. Positive sputum, Gaffky IV.

Re-examination prior to the proteogen therapy: More marked activity over all trunks of left upper lobe, cavity signs still present anteriorly as well as posteriorly. Right lung, activity present over upper lobe, involving all trunks; active changes still persistent over upper half of right lower, and middle lobe areas. Left base relatively clear. Temperature normal, pulse 88, respiration 22, weight 124¾, remaining the same as on admission. Sputum Gaffky VI 3 ozs. (90 cc.).

Another examination on January 13, 1919, gave similar findings as at the preceding one, but more extensive involvement and activity over entire right lower lobe with signs of bronchopneumonia, and activity extending into upper half of left lower lobe, suggesting positive changes over at least seventeen bronchial trunks. Temperature normal, pulse 100, respiration 22, weight 126 pounds. Sputum in twenty-four hours, four ounces (120 cc.), purulent, containing a number of bacilli. Cough very obstinate, uncontrollable except by repeated doses of codeine and heroine.

Sixteen injections of the vegetable protein were given from January 16 to February 19, 1919, beginning with 8 minims, running up to 16 for six doses, then reduced to 12 minims for the last two.

According to the patient's statements, the amount of sputum was decreased for about forty-eight hours after an injection. After this period there was an increase. The general tiredness, especially in the morning, was less noticeable. There was slight discomfort existing for the first twenty-four hours at the site of injection, where redness and moderate muscular and subcutaneous infiltration could be noticed.

On February 22 the dose was increased to 24 minims, then reduced to 12, and again increased to 16, the course of protein treatment terminating on April 1. On March 20 the patient reported more severe and not very productive cough, while in regard to the general condition no further change could be noticed. So far the injections had been given alternatively in each arm. Following the dose of March 29, while the same precautions in disinfecting the site of injection were carried out, the reaction was more marked, namely intense infiltration, pain, and tenderness prevailing over a large area. The next injection given into the other normally looking arm was equally followed by a similar local reaction. Antiphlogistic application of saturated ammonium sulphate solution to the intensely inflamed areas was not followed by any improvement, pain persisting, with unusually high temperature for the next three days (101°), followed by a decline in the febrile reaction. An incision over the right arm gave the necrotic area an opportunity to empty a yellow, purulent matter, the microscopic examination of which showed staphylococci present. The cup-shaped defect with undermined borders slowly granulated and closed. The same process took place in the left arm, requiring incision and escape of the yellowish, creamy, grumous contents. The increased pulse rate diminished, so did the respiratory rate, while the weight up to April 23 had diminished two pounds.

With the discontinuation of the injections, however, the cough and expectoration of more purulent matter increased, averaging from 150 to 180 cc. daily, and while before the injections were sufficient to check cough and expectoration, the ordinary expectorants and sedatives had to be given.

The blood pressure variations noted were: *Before treatment:* systolic, 120-135; diastolic, 65-80; pulse pressure, 47-65; *during treatment:* systolic, 118-124; diastolic, 64-84; pulse pressure, 36-50; *after treatment:* systolie, 114-130; diastolic, 64-80; pulse pressure, 48-60.

The chest examination made twenty-three days after the last injection revealed the following facts: *Right upper lobe,* anteriorly: No signs of activity, but sclerosis in areas corresponding to vertebral and first interspace trunks. *Posteriorly:* Moderate activity with sclerosis of vertebral trunk, diminished intensity of breath sounds over first interspace trunk, moderate activity over posterior branch of second interspace trunk. *Right lower lobe:* Activity and fibrosis over upper half of that lobe, apical trunk and median basal trunks, dry pleurisy with friction sounds.

Left lung, upper lobe: Marked activity with sounds suggesting multilocular cavities (?) in both vertebral, first, and second interspace trunks. *Lower lobe:* Increased breath sound and whispered voice conduction in upper half of that lobe. Apical trunk, moderately active, persistent rales after cough. Emphysematous type of breathing over left base. Heart relative dullness, slightly increased toward the left side. Sounds decidedly more distinct and vigorous.

The patient's temperature pursued a regular course, pulse maintained a tendency toward irregularity and acceleration. The weight, however, declined. Ten weeks after the injections had been stopped the weight was only four pounds above the one recorded immediately preceding the injection treatment. Five weeks having elapsed without proteogen medication, cough and sputum were remarkably pronounced, a daily average of 180 cc. being expectorated.

Generally speaking, the patient improved. Before the injection treatment he was confined and very weak for even the slightest effort. Five weeks after the last injection he was up and around, started slowly with work not more than one-half hour a day, gradually increasing the same until capable of accomplishing six to eight hours' work daily, helping the pharmacist in his department for over nine months without any inconvenience, except a slight hemorrhage on September 26, 1919.

Physical examination carefully made by our expert resident physician, Dr. C. C. Conn, was *absolute negative* regarding any *trace of clinical activity* (October 29, 1919). *Fibrous interstitial changes,* probably sclerosis, could be noticed over right upper lobe, corresponding to vertebral and first interspace trunks. Right lower lobe suggested fibrosis in apiceal and median basal trunks and thickened pleura. *Left lung, upper lobe,* had also become sclerotic, corresponding to the vertebral trunks not excluding cavitation, with less destructive transformation in the domain of the first, perhaps the second interspace trunks more so anteriorly than posteriorly.

While he was getting over a cold the physical examination on December 21, 1919, revealed diffuse activity over both upper and upper half of right lower lobe; rales after cough. It may be that the protein treatment ought to be resumed after a suitable interval so that its effect will not be limited.

The above cases are cited only as examples of our study, and though their histories may reveal some interesting details for the specialist, but not carry weight with the average practising physician, a brief review of our investigation may be of use.

The cases which may benefit by the treatment must be properly investigated and should not be chosen from clinical material in which the pulmonary process has extended into the apices of one or both lower lobes. Furthermore, the activity should not be so intense, since with an overdose or too closely followed injections, the parenchymatous lung reaction may be more than the patient can stand. The toxemia, vasomotor depression, and myocardial degeneration should not be too pronounced as the reaction of the patient may equally become too strong for the patient to overcome. The dose and the time of injection should be carefully controlled. Institutional treatment in addition would offer the best chances for improvement.

As shown in a number of instances the following possibilities may be, but are not necessarily always to be anticipated: Reduction of cough, expectoration, lessened feeling of general tiredness, while physically a tendency towards sclerosis and gradual decrease of clinical activity may result from a carefully conducted course of injections.

Remembering, however, the frequent instances in which cases of pulmonary tuberculosis are not properly diagnosed as to intensity and extent of the pathological lesions, the warning is justified not to try the medication in doubtful cases in which a correct understanding of the involvement has not been reached, or where the patient's cooperation in submitting without objection to the physician's orders remain doubtful.

The scientific conception upon which the proteogen therapy is based represents a remarkable advance in therapeutics to overcome tubercular infection, as it produces a bactericidal action upon the tubercle bacillus, dissociates its fatty capsulet, and eliminates the toxins so produced.

There seems to exist a possibility of improving not too far advanced tuberculous patients by a carefully conducted series of injections. The dose, however, is individually different and requires a dose supervision which only further studies will ascertain. It cannot be the aim of the scientific clinician to mention only the good qualities a new preparation may possess and pass lightly over the dangers of new methods. The truth, as in any other domain of science, is the first object of the investigator, and as in our progress we learn more, it may help the medical profession and the patients anxious to regain their former health.

THE ROOTS OF EVIL.

By W. B. KONKLE, M.D.,
MONTOURSVLLE, PA.

FIRST causes are the only real causes. Radical reform is the sole enduring reform. Success in the annihilation of wrong will be commensurate with the thoroughness attained in the destruction of its roots—it is hard to kill it from the top. Error is like the Canada thistle—you can not suppress it by retrenchment; to be done with it you must eradicate it. As assiduously and persistently as the student of language hunts down Greek roots should reformers seek for the roots of evil. Praise and honor to the benevolence that strives to rescue victims from the raging flood. But more sensible and scientific is the philanthropy which from far up the stream along all its course at each point of peril safeguards the treacherous banks. As to disease and vice alike prevention is the master-word.

The social evil, so called, perennially has been scrutinized and combated from every angle of science from which antagonism may be brought to bear. Humanitarians of all classes recognize it as the chiefest bane and scourge of the race. As a source of woe and wreck and ruin it is mankind's mightiest, deadliest foe. Oh! the pain and grief, the disease and degeneracy, the degradation, the despair, the death that constitute the deplorable fruit of this tree of vice! Truly it is right, proper, and a bounden duty to continue direct attack upon the evil as itself a baleful cause. But may there not be some risk of overlooking the pertinent fact that it is as well an effect, a result?—that this tree in turn has roots?

A principal and potent root of the dire evil in question is neglect of timely, adequate, persistent supervision and instruction of childhood. Science would extend her formative and controlling hand even to the domain of genetics, essaying to mould the human stock in its very generation; and that, forsooth, is logical and wise. But in any event, she should meet the child at its entrance into the world, spread over it her aegis, guide it with her hand, walking as a mentor by its side through all its early years. Mastery of forest fire is absolute in mastery of the initial spark.

The fires of vice are lighted and kindled into urgency and dominancy during childhood and youth —usually so. Lamentable to relate, without any counter-protective influence of indoctrination, or persuasion, or discipline in the general case, the flames spread from child to child, filth befouled information, corrupt reflections, besotting imaginations, debasing practices progressively gaining ascendency over the young life until enslavement to them can be broken alone by revolt, robust and resolute, of a personality naturally upright and noble. Though complete and accurate knowledge comes, alas! how often it comes only through bitter experience, and comes too late to save! In a large proportion of instances, albeit the evil may change form, take anon variant departure, manifest development of subtility and refinement, yet will any transformation thereof involve merely questions of guise, taste, and opportunity corresponding to differences of age, culture, and association. The fires once started are prone to burn on while strength and force can be taxed for fuel.

Yes, discouragingly futile, indeed, and baleful to hope, have been the manifold attempts to subdue, or even control, the social evil at its conflagration stage. Contemplating such effort, the skeptic gravely shakes his head, the cynic sneers, the pessimist muffles himself in a mantle of gloom. The optimist perseveres; but his task well nigh matches the task of the Danaïdes, and his labor parallels Sysiphus' everlasting toil. And any restatement of the situation must be sheerest commonplace. In justification of his aforepresented platitudes on the subject the writer would plead alone a desire to again emphasize the expediency, aye, the necessity, of attacking the evil at its source.

To asseverate broadly that childhood and youth should be carefully guided and guarded is merely to utter an axiomatic generality also smacking of triteness. In better form, and more to the point, will be plain, frank particularization.

Beginning with the earliest postnatal period of life, the dawn of infancy, it should be definitely ascertained as to whether the sexual structures are normal and healthy. Any deviation from the norm should be corrected, any focus of disease should be removed. This is of utmost importance. A fault here, in itself perhaps not serious, may originate disastrous disturbance and irregularity in both the physiologic and the psychologic activities. A morbid stimulus transmitted from these parts may be a cause of shocking excesses, obsessions, perversions. Especially do our authorities on andrology insist that superirritability in the male of the tissues in question produces not unfrequently a staggering toll of harm, misery, anguish, attributed ill-advisedly to the operations of viciousness. Parenthetically we presume to remark that such local irritation may account for much of the

lasciviousness sometimes discovered in elderly husbands, and for most of the pruriency ofttimes exhibited by old widowers. Those of the latter class are apt to perform like the writer's five-year-old nephew, who, having been given a dime to spend in the ten-cent store, set his heart upon the first thing that met his eye when he entered, which happened to be a big tin funnel. A prostate on the rampage can be a very Turk of a tyrant. Of course, as to both the mentioned classes, associated head weakness is a determinative co-factor in disgraceful and unworthy conduct. Says La Rochefoucauld, *"En vieillissant, on devient plus fou et plus sage"*; and again, *"Les vieux fous sont plus fous que les jeunes."*

The child should not be allowed to fix its attention upon its private parts. Interest should be so turned in other directions, and amusement so drawn from other things, that such tendency be forestalled. Above all, prevention of habitual handling of those parts is superlatively essential. Stern rebuke and sharp discipline dare not be spared short of unqualified accomplishment of such purpose. As filth eating, or thumb sucking, or the putting of foreign bodies into the ears or nose would be energetically dealt with, so must the propensity under consideration be opposed with concern and vigor proportionate to the potential peril therein implied. In this regard upon the mother devolves a burden of duty which cannot be delegated to another.

Chillren should not commingle by themselves—be together without oversight. An impure child will quite certainly contaminate its companions if given a chance to transmit the poison with which, unfortunately, it has itself been infected. Unclean thoughts and debasing practices are the most contagious, as well as the most pernicious, of the ills to which childhood is peculiarly susceptible. Let the mother discerningly select her child's playmates—that is indeed well. But let her not trust her choice as unerring. Some little sullied life, pathetic, pitiful, and yet terrible, may escape her scrutiny. And then her heart may be made to bleed by stains afterward revealed on the newly expanding soul so closely linked to her own.

The child should be kept busy seeing, and hearing, and doing what he *ought* to see, and hear, and do. That policy will have, truly, great positive value. But it will have a negative value at least equally as marked. It will preclude the seeing, and the hearing, and the doing of that which he ought *not* to see, and hear, and do. Preoccupation of the mind with the good is a sure condition of exclusion of the bad.

The snares of childhood passed, those in the path of youth are to be next shunned or circumvented. At this period of life individual reason and responsibility appear in the foreground as elements in the problem of morals. The young person *finds* himself—becomes conscious, as it were, of self-sovereignty, self-determination. Communing with his inner self, surveying his powers, he feels the thrill of the thought throbbing in Henley's lines:

"I am the master of my fate;
I am the captain of my soul."

Persuasion must now replace dictation as a method of moulding character. As to the aim and form of such persuasion, let our study be confined to the boy alone. In ultimate reaction, good boys keep the girls good.

Upon the youth should be impressed the seemliness and the imperativeness of understanding, respecting, safeguarding his own person. He should be taught to take pride in developing his body to the highest standard feasible of perfection and effectiveness, to maintain his physique in the finest form and condition practicable, to scorn any act that might entail physical debasement and degradation. To this end should be earnestly encouraged clean, sturdy, manly sports, especially those of out of doors. Let ever be held up before him the inspiring ideal of making and keeping himself a fit champion of truth and right, a worthy warrior of the Lord of Hosts.

The lad should be solemnly charged to cultivate and cherish the higher affections. A philosophy grossly materialistic, and hence soulless, has professed to trace all that is purest and best in humanity back to an origin in primal animal instinct. The theory may be well founded, though speculative, far-fetched, foggy, as propositions of the sort usually are. But for the nonce conceding the thesis, still will chivalric gallantry paying homage to woman be noble, heroic, though in the last analysis springing from sex conditions and relations. Even though grounded in the earthly, yet perennially heavenly will be love toward sister, mother, sweetheart, wife. Is a carnation or a rose less fragrant, less beautiful, less stainless because its roots are embedded in the dirt? And unshaken by time's upheavals, untouched by any profaning hand, let home remain earth's holy place forever—home, that consecrated spot, more endeared than *any* other, where fondest affections are enshrined; where, under the enchantment wrought upon the scene by the rapturously breathed names of loved ones, the world's storms are quelled, and Eden blooms again beneath cloudless skies.

The boy should be trained to a sense of honor and veneration for the female sex. He should be advised to half pity and half despise bad girls. He should be taught to treat good girls with knightly deference and regard—that he must defend them—that a Sir Walter Raleigh will always fling his mantle in the mud for a virgin queen to walk over. Obviously this attitude implies looking up to woman as a being something superior. Just how the equalizing, the leveling *down* process, may affect that idea is uncertain. If the writer has any doubt in the matter, he begs leave to protest that his doubt at least comes from reverence for, and not from underestimation of, the mothers of our race. Whatever question there may be about the glory and profit of transforming goddesses into peeresses, however alarming it may seem for woman to descend from her serene dais to the tumultous floor, yet must the boys still be taught to exalt, to etherialize the girls. It may prove strange and embarrassing to them to court on a dead level, but their pluck and resourcefulness will bring them creditably through the ordeal!

Have you hunted bees? We *line* them. We painstakingly, patiently work until we have determined the *line*. That line we then follow unswervingly, though in its forward stretch are thickets

and brambles and morasses and rocks and waterways and bluffs and chasms. In dealing with the social evil the first consideration is to get the *line*. The writer contends that cure is *not* the line—that it will only lead you in a circle, until at last you come back to where you started. He believes that prevention *is* a line—that it is *the* line. A long, hard line, you say. Ah! but that is bee hunting! The eradication of vice is a process, not an act—its promotion should be evolutionary, not revolutionary. Very few evils can be strangulated by eighteenth amendments. Or, rather, the advent of the eighteenth amendment should be not far from the end of the line—it should constitute the *coup de grace* of the evil being run down. Hold on, toil on—that is all there is to do. Meanwhile the bells of progress will continue to peal, ringing out old wrong, ringing in new right. And every step along the true course will be a step nearer the goal. And every step will be a pathfinder's step.

MALNUTRITION FROM UNDERFEEDING IN A TWO AND ONE-HALF YEAR OLD CHILD.*

By B. K. RACHFORD, M.D.,

CINCINNATI, OHIO.

PROFESSOR OF PEDIATRICS, UNIVERSITY OF CINCINNATI.

April 12, 1919, white, male child, 2½ years of age. Referred to me by Dr. Albert Freiberg. Was brought to my office in his father's arms because he could not walk. The child was malnourished; from the time he was eight months of age he had suffered more or less from intestinal fermentation, and for that reason had been underfed.

Five weeks ago he commenced to limp in his right leg, and the lower portion of the leg, especially about the ankle, became tender and swollen. This condition rapidly increased so that the child was unable to walk.

Previous History.—The mother nursed the child from birth until he was eight months of age; at this time he was weaned and placed upon modified milk. He soon developed a gastrointestinal fermentation, which has continued from that time until the present. To overcome this condition he was given skimmed certified milk and Mellin's Food. Soon after orange juice was added to his diet. From the age of fourteen months until the present time his diet has consisted almost exclusively of three pints of skimmed milk daily, beef juice, zwieback, rice, and cream of wheat. He never could take oatmeal or eggs. The mother states that other foods were tried from time to time, but that any deviation from the above diet always produced loose, foamy, and offensive stools, and even when taking the above-named foods it was necessary to give him intestinal antiseptics, and at times bismuth in some form, to prevent loose bowel movements.

Six weeks ago he had an attack of influenza, which increased the intestinal disturbance, produced a slight cough, and an elevation of temperature from time to time. These symptoms had continued up to the present time.

On physical examination I found the child to be rather poorly nourished. He was pale and anemic looking. He was rachitic; his chest, arms and legs were rather undeveloped; the rachitic rosary could be felt; his abdomen was very much distended (pot-belly), and there was a flaring of the lower portions of the ribs. The superficial lymphatic glands were not noticeably enlarged, except the posterior cervicals, which were slightly increased in size. The superficial veins of his face were quite noticeable. The urine was normal. The heart and lungs were normal. He had good movement of every portion of his body except his right leg, which, below the knee, was swollen and painful to the touch. The swelling and tenderness above the right ankle were quite marked. The right foot was held in marked valgus. The prepuce was irritated, red and swollen, and had been so for a number of months.

Blood examination.—Hemoglobin 75 to 80 per cent.; red corpuscles 4,730,000; white corpuscles 13,400, polymorphonuclears 35 per cent., small lymphocytes 41 per cent., large lymphocytes 23 per cent., mononuclears 1 per cent., eosinophiles 0, basophiles 0 per cent.

Treatment.—A dose of castor oil, this to be repeated once a week, if necessary, to clear the intestinal canal of mucus. Three grains of saccharated carbonate of iron, and 1½ grains of iodonucleoids to be given in a teaspoonful of maltine, and hypophosphites three times a day after eating.

Diet:—One quart of peptonized milk daily, rice, cream of wheat, baked potatoes, new peas, and string beans. Vegetables to be well-cooked, mashed, and put through a colander.

April 17. A Von Pirquet test was negative. An examination of the stool showed the above foods were well digested; no parasites were found. On this date slightly cooked scraped beef was added to his diet.

April 22, 25 and 29 an examination of the stool showed fairly well-formed intestinal discharges, with little or no evidences of undigested food.

April 29. A second Von Pirquet was negative. At this time the child's general appearance was greatly improved. His pallor had begun to disappear. He had a good appetite, and with the aid of a small leather brace, prescribed by Dr. Albert Freiberg, he had begun to walk. The swelling and redness of the prepuce noted on his first visit quickly disappeared.

June 14. The child now with the aid of his brace was walking fairly well. The swelling, pain and tenderness in his right leg and ankle, which began to improve almost at once, after he was put under treatment, had now almost entirely disappeared. There was only a slight suggestion of puffiness above the ankle. The improvement in his general condition was very great; apart from his slight lameness and the abdominal distention, his appearance was that of a normal child.

The blood examination made at this time was as follows:—hemoglobin 90 per cent.; red corpuscles 5,550,000; white corpuscles 8,200, polymorphonuclears 30 per cent., small lymphocytes 34 per cent., large lymphocytes 22 per cent., mononuclears 9 per cent., eosinophiles 3 per cent., basophiles 2 per cent. This blood examination, as compared with the one made two months before, showed a marked increase in the hemoglobin and in the number of red blood corpuscles. There was also a very marked decrease in the number of white blood corpuscles with a decrease in the relative percentage of lymphocytes.

At this time the boy was on the same medication prescribed above. The castor oil prescribed at his first visit was given only a few times. The iron, iodonucleoids and maltine, which he was still taking, were ordered continued through the summer. His food now consisted of one quart of peptonized milk daily, meat every day, either lamb, chicken or beef, almost all kinds of fresh vegetables, orange juice, apple sauce, cereals, bread and toast.

December 29, 1919. He went through the summer without illness, except for a slight intestinal disturbance, which lasted for a few days. During the fall he had a cold once or twice, which did not disturb his digestion.

The boy to-day is apparently as well and strong as any child of his age. His skin is rosy, his body well-formed. There is no longer any evidence of trouble in the right leg. He has perfect action of all parts of his body. He ran about and played "catcher" through my office with the activity of a normal boy. His mother, however, reports that he is not yet able to take milk in any form except peptonized milk, of which he still continues to take a quart a day.

His diet at the present time, in addition to the peptonized milk, includes orange juice, cooked fruits, vegetables, cereals, bread, beef, lamb, chicken and desserts containing egg, but raw milk and ice cream are still excluded from his diet.

*Read by title at the annual meeting of the American Pediatric Society, May 31-June 2, 1920.

His urine is normal, his bowels move once a day without laxatives. Blood examination: Hemoglobin 80 per cent.; red blood corpuscles 4,937,000; white blood corpuscles 9,060, polymorphonuclears 49 per cent., small lymphocytes 23 per cent., large lymphocytes 12 per cent., mononuclears 11 per cent., eosinophiles 5 per cent.

On dismissing this patient I advised his mother to discontinue the peptonized milk gradually and add eggs to his diet.

From the time this boy came under my observation until his discharge, I was very much interested in his rapid progress toward recovery, and especially in the blood changes here recorded. On my first examination his previous history, his general appearance and the blood picture were strongly suggestive of tuberculosis, but I now believe that tuberculosis played no part in his malnutrition. I think that not only the blood changes but the whole clinical picture above recorded were due to malnutrition from intestinal fermentation and insufficient and improper food.

I also believe that the prompt recovery which resulted in this boy's case was largely brought about by the use of peptonized milk, which enabled him to take meat, vegetables, fruit, and cereals without causing intestinal disturbance. I make this note because I feel that the prejudice among the profession against peptonized milk, in the treatment of malnutrition, is unjustified. It makes not only the giving of milk in many of these cases possible, but it also greatly increases the range of the child's digestive capacity for other foods.

LIVINGSTON BUILDING,
SEVENTH AND RICE STREETS.

DREAMS AS THE CAUSE OF DEATH AND DISEASE.

BY MAURICE CHIDECKEL, M.D.,
BALTIMORE, MD.

WHETHER dreams are divinations or predictions, foretelling events to come, is no concern of this paper. The object is to show the baneful effects of dreams in individuals afflicted with cardiac disease and hypertension, leading to acute dilatation, rupture of a cerebral artery, and death; and that in many diseases of the nervous system dreams are the etiological factors, caused in most cases by gastrointestinal disturbances.

The man who composed the book of Daniel must have had some conception of its emanation from the brain. The king speaks of the "visions of my head upon my bed." We know now that dream is the predominance of the motor over the sensory side, and, that it is as a whole an expression of clouded consciousness with disorientation in whole or in part. While the sleeper is tormented by a terrifying dream, making distressing inspiratory noises, the cortical sense areas are irritated, the inhibitory center becomes disarranged, and the individual will awaken exhausted from his exciting experience, his heart beats and pulse rate doubled. If the irritation continues he will keep on running or walking in a mental fog. In one case it has taken three strong men to keep a perfectly normal individual from committing violence when awakened from a dream that he was being attacked by a highwayman.

If a patient with a moderately dilated heart will drop dead during a fit of excitement from acute dilatation, or one with a hypertension from a ruptured cerebral vessel, why cannot other patients suffering from the same diseases die from a similar cause in their sleep?

A man with a compensatory mitral leak and moderately dilated heart climbs up nightly three flights of steps to his bedroom, having only slight dyspnea, and one morning he is found dead in bed. If exertion did not kill him why has rest done it? The only plausible answer is that he died from acute dilatation caused by the excitement of a terrifying dream.

The vagus has a deep motor origin, and is primarily an inhibition nerve. The motor side always predominating in dreams, the rôle of the pneumogastric in dreams is self-evident. As the deep cardiac plexus, a tributary of the vagus is situated in the concavity of the arch of the aorta, and as the anterior and posterior coronary plexuses also originate from the vagus, the effect of an exciting dream on the heart cannot be exaggerated.

Repeated tormenting dreams mean repeated cortical irritations, and must necessarily do damage to the cortex and impair permanently the nerve fibers and nerve cells. The cortex is now known to represent a complex mass of sense centers, known as the somasthetic area, extending in front of the central fissure, being directly connected with the fissures of Sylvius and Rolando. Hence any damage in any area, any irritation or injury to any part must have a direct or indirect effect upon the whole make-up of our patient.

A man with a chronic nephritis and a compensatory hypertension of 170/110 led a quiet life and felt fairly well. His next door neighbor was killed by robbers during one night. A few days later he was heard to scream in his sleep, articulating the word "police" distinctly. By the time his bed was reached he was dead. The excitement of his dream led to an enormous increase of his pressure rupturing a large cerebral artery and killing him.

Numerous cases observed within the last ten years, dispensary and private, have brought the conviction that many nervous ailments in children and adults have originated from dreams, resulting in pavus nocturnus, narcolepsy, melancholy, and epilepsy, due to continuous cortical irritations, caused by dreams that were tormenting and exciting.

The majority of such dreams in infancy and adolescence arise from disturbances of the alimentary tract. Gastrointestinal disorders, as is well known, are the chief exciting causes of convulsions in children. The reason why intestinal worms and improper food cause these cerebral manifestations is due to the visceral sensory distribution, causing motor disturbances. In adults these motor irritations will show themselves in a lesser degree—exciting dreams.

Repeated convulsions in a child, damaging the cortex, lay the foundation for future epileptic seizures. Repeated tormenting dreams in adults, damaging the cortex, will lead to many and various nervous manifestations in later life.

In a study of 21 cases of epileptic seizures in children, a definite history has been obtained in 14. In all of these 14 the mothers related that the children would jump and cry out from their sleep in early infancy. Nine of the 14 were bottle-fed

babies with no system of feeding and no preparation of the milk. Six were breast-fed children who were never nursed regularly, all having practically nursed the whole of the night. At the ages ranging from 18 months to 3½ years, 18 of the 21 had night terrors. Only 2 of the 21 had enlarged adenoids and 4 had enlarged tonsils. Convulsive seizures began at 5 in the youngest and at 8 in the oldest. Twelve had nocturnal and 9 had diurnal convulsions. Physical examination was negative in all but one, whose thyroid was palpable and who had a soft systolic blow. None had albuminuria or casts except when the urine was examined soon after the seizure. The conclusion drawn was that, owing to faulty digestion and abuse of the alimentary tract, these children had vague, terrifying dreams in their early infancy, causing a steady and gradual irritation of the cortex. The irritation having continued and with the increasing age of the child the dreams having assumed a more definite form, the cortical cells were sufficiently damaged to cause night terrors. With the continuation of these terrors enough damage was done to the motor area of the brain to lead to convulsions.

In cardiac disease in its various forms and in hypertension with and without renal trouble, the emotional effects were observed in 70 of the first and 38 in the second. In each case the cardiac dullness increased, the murmur, if present, became louder and in some cases the cardiac cycle became so disturbed that the nature of the murmur could not be made out. In each case of hypertension the rise in pressure was from 10 to 125 mm. One case will be cited as an example:

A patient came to the office taking his little son with him, but leaving him outside to play. He had a chronic interstitial nephritis, a relative mitral insufficiency, and a pressure of 160/100. While the reading of the pressure was taken, a child run over by an automobile was brought in, with the usual commotion that accompanies such cases. The reading immediately rose to 290. It went back to its previous reading on learning that the child injured was not his. The area of his cardiac dullness has increased considerably, and his mitral murmur became loud and kept on for some time. If this man is to dream that his child was run over, he most likely will die, either from acute dilatation or apoplexy.

The following case is illustrative:

A woman with a marked mitral stenosis was awakened from a dream that the house was burning. She was exhausted, short of breath, but went to sleep again. She soon screamed and was again awakened, having had a repetition of the same dream. The third time she went to sleep she expired after a few suppressed loud grunts she attempted to make.

In all the cases of exciting dreams a history of dyspepsia or an overloaded stomach is given, no terrifying dreams occurring on a fasting stomach.

Inquiry in a thoroughly digitalized patient who was worse every morning after a night's rest elicited the information that she was tortured by dreams. Every morning the amount of the dilatation was more, sometimes considerably so, than at night. Food was forbidden four hours before bedtime, and an enema was given one hour before sleep; her dreams then ceased and she immediately showed signs of improvement.

Résumé: Dreams in children are caused by faulty digestion.

They are possible causes of serious cerebral lesions due to irreparable damage to the cortex.

Dreams in adults are mostly due to the same cause.

Repeated tormenting dreams will cause even cortical injury in adults leading to cerebral lesions of a serious nature in later life.

Patients with heart disease and high blood pressure may be killed in their sleep by a terrifying dream.

That patients suffering from cardiac trouble or hypertension due to any cause shall not be allowed to eat at least four hours before sleep.

2328 MADISON AVENUE.

THE CAUSE OF X-RAY BURNS.

BY JOHN REMER, M.D.,

ROENTGENOLOGIST, VANDERBILT CLINIC, COLLEGE OF PHYSICIANS AND SURGEONS, COLUMBIA UNIVERSITY,

AND

W. D. WITHERBEE, M.D.,

NEW YORK.

ROENTGENOLOGIST ROCKEFELLER INSTITUTE.

DURING the early days of Roentgenology, when the gas *x*-ray tube was all there was, we were especially warned against the use of any factors with very low voltages, for the reason that low voltages produce an immense number of rays of low penetration which are absorbed by the skin and hence more liable to cause an *x*-ray burn than the high voltages whose rays are of high penetration and not absorbed by the skin.

The above theory has been handed down from year to year and it is only within the last few years that the fallacy of it has been realized.

Soon after the announcement of Saboraud and Noire method of treatment of ringworm of the scalp, many attempted to carry out the procedure with an *x*-ray coil instead of a static machine as used by the originators. This resulted in overdosage and permanent baldness in many of the cases. The reason for this was the failure of the operator of the coil to maintain a constant high voltage for any length of time as compared with the tube maintained by the static machine.

This drop in voltage in the gas tube no doubt increases the number of low penetrating rays, and it was naturally concluded from the theory of absorption that they were the cause of the permanent alopecia or *x*-ray burn. In order to test out this theory, the following experiment was made with a Coolidge Tube and reported in the June issue of 1917 of the *American Journal of Roentgenology:*

Four areas of a patient's back were treated with the following factors for each area:

MA Sp. G. T

No. 1. $\frac{3 \times 3 \times 5}{8D \times 8D} = 1¼$ skin units = 5H;

No. 2. $\frac{3 \times 6 \times 2½}{8 \times 8} = 1¼$ skin units = 5H;

No. 3. $\frac{3 \times 4½ \times 3⅓}{8 \times 8} = 1¼$ skin units = 5H;

No. 4. $\frac{3 \times 9 \times 1⅔}{8 \times 8} = 1¼$ skin units = 5H.

The photograph (Fig. 1) of the patient taken ten

days after treatment demonstrates that all areas coincide, yet in two of them, namely No. 2 and No. 4, the spark gap was doubled and one-half the time taken for exposure that was given in No. 1 and No. 3, respectively. It therefore follows that if the spark gap is doubled and the time reduced one-half, the same degree of erythema will be produced, other factors remaining constant.

From the standpoint of quality of *x*-ray in the above experiment, the formula with 6-in. and 9-in. spark gaps (No. 2 and No. 4) should give a very large percentage of penetrating rays as compared with the 3-in. and 4½-in. (No. 1 and No. 3), and hence one would expect that these penetrating rays derived from the higher spark gaps, 6 and 9 (No. 2 and No. 4) would pass through the skin and take much longer to produce the same degree of erythema as that followed by the use of 3 and 4½-in. formulæ (No. 1 and No. 3). Exactly the reverse proves true. For it took just one-half the time for the same biological effect in the doubled spark gaps (No. 2 and No. 4) as it did in the 3 and 4½-in. (No. 1 and No. 3) formulæ.

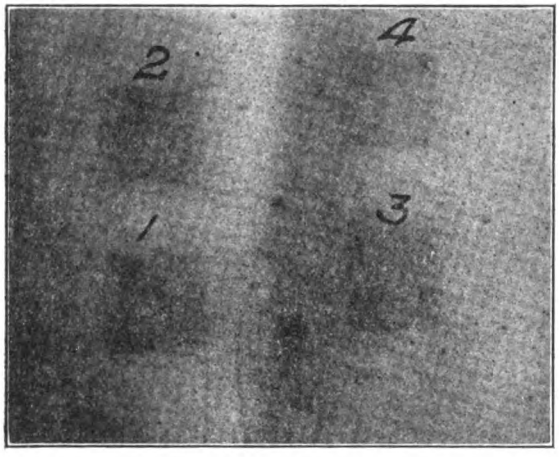

FIG. 1.

It is, therefore, apparent that the quality of the ray and the absorption of those of long wave length have little to do with the biological effects in the skin. On the other hand, it seems that the factor which determines this effect is solely the quantity of *x*-ray reaching the skin, for it is obvious that a high spark gap produces more rays that reach the skin than the same dose with a low spark gap.

Recently we have tried out the following factors on the skin of a patient's back:

$$\frac{\text{MA Sp. G T}}{5 \times 9 \times 9/16 \text{ min.}}{6 \times 6 \text{ D}} =$$

33¾ sec. = 1¼ skin unit = 5 H.

Tris is an erythema dose without a filter.[1] The filtered erythema dose using 3 mm. of aluminum is as follows:

$$\frac{\text{MA Sp. G T}}{5 \times 9 \times 7.7 \text{ min.}}{6 \text{ D}} =$$

2½ skin units = 10 H.

In the photograph (Fig. 2) both areas of erythema are identical. No. 1 was produced by the unfiltered erythema dose; No. 2 by the filtered erythema dose. Biologically, to all appearances, the erythema produced in 33¾ seconds by the unfiltered ray is the same as that produced in 7 minutes and 42 seconds by the filtered.

If the voltage determines the quality of the ray, then in this experiment the voltage is the same in

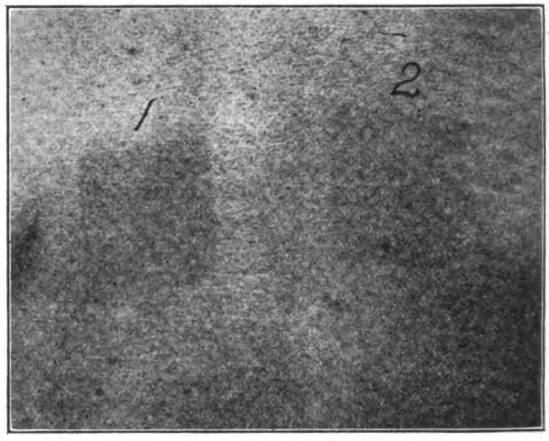

FIG. 2.

both instances; the only difference is the interposition of 3 mm. of aluminum and about ten times longer exposure for the filtered dose as the unfiltered. Here again the quantity of *x*-ray reaching the skin is materially lessened by the aluminum, thus making the enormous difference in the time of exposure.

This dose with 3 mm. of aluminum takes a little over ten times as long to produce an erythema as it does without aluminum. In speaking of this dose some writers would say that they gave ten erythema doses. This statement without qualification is misleading. In reality the effects, so far as the skin reaction is concerned, are identical. If then the filtered and unfiltered erythemas are the same, the only difference being in the number of rays reaching the skin, thus increasing the time, why is it that a filtered dose is five or ten or any other number of erythema doses? The fact remains that biologically filtered and unfiltered erythemas are identical, as exemplified in Experiment No. 2, illustrated in Fig. 2; that 1¼ skin units unfiltered = 5 H or one erythema dose, also that 2½ skin units filtered or one filtered erythema dose.

By increasing the thickness of the filter and decreasing the spark gap the time necessary for a filtered erythema dose, namely 2½ skin units can be progressively increased. Although decreasing the spark gap in unfiltered dosage lengthens the time of exposure for an erythema dose, the time ratio between the lower voltages and the thickness of the filter is many times greater than those of the higher voltages. Therefore, one might select a formula with a very low voltage and be able to say that one gave forty or fifty erythema doses.

If then, in describing the *technique of filtered dosage*[2] we adopt 2½ skin units as the standard for an erythema dose, we can use it with the same degree of accuracy as we have the erythema dose of unfiltered dosage.

A SUGGESTION FOR A DIETETIC PRESCRIPTION BLANK.

By EDWARD E. CORNWALL, M.D., F.A.C.P.,

BROOKLYN, N. Y.

THE dietetic prescription blank here presented is designed especially for the purpose of making easy the computation of the food values of definitely prescribed diets. A representative list of commonly used food stuffs is given, sufficiently extensive to meet the dietetic requirements in a large proportion of invalid conditions, and with it, conveniently arranged for easy reference, is given the protein, fat and carbohydrate content and caloric value of thirty-gram or one-ounce portions of these articles. Spaces are provided for stating the quantities of prescribed articles in relation to times of feeding or meals, and also of the protein, fat and carbohydrate content and caloric value of the day's rations of each article prescribed and of the whole prescription. In the case of articles which are prescribed to be taken not every day, but a specified number of times a week (for the noting of which limitation a space is provided), the amounts of the food principles involved require adjustment to the daily ration scheme; and it is advisable to draw a line around the figures relating to the quantities and food values of such articles; and a similar circumscription may be used to isolate the quantity and value figures of articles allowed in alternation.

The hour of feeding may be specifically designated, or, if regular meals are given, the letters B, D and S or L (for breakfast, dinner and supper or lunch), may be written in the spaces for hours of feeding; and if regular meals with additional feedings between meals are prescribed, the hours for the additional feedings may be written in the spaces after the B, D and S or L, or in chronological order.

If more than eight feedings in twenty-four hours are desired, the quantities of food and number of times of feeding daily, with the intervals or the hours, may be stated on the same line as the food article; as for example, *Milk*....8 oz., q.2.h between 7 A. M. and 9 P. M., and at 1 A. M. and 4 A. M.; or these extra directions may be written in the blank space at the bottom of the page, and always so if the article is one not on the printed list; as for example, *Orangeade*....7 oz. at 10 A. M., 2 P. M., 6 P. M. In the majority of cases the number of feedings required daily will not exceed eight, for which spaces are provided.

Quantities may be ordered in grams or ounces, by drawing a line through the contrary word. Articles in a group may be excluded by scratching. Adjacent groups may be included by a bracket to form a field of choice; as for example, the four lines of milk preparations in the first "compartment" may be bracketed to mean that the feeding

.5	0	1	5	Lettuce, cabbage, celery, endive, tomato, (raw)														
0	0	1	5	Grape fruit, lemon														
0	0	2	10	Orange, peach, pineapple, muskmelon														
0	0	3	15	Apple, pear, huckleberry														
0	0	5	25	Apple, (baked), prunes, (boiled), banana, grapes														
0	0	0	0	Tea, coffee, cocoa shells														
0	0	0	0	Broth of beef, mutton, lamb, chicken, clam														
0	0	1	5	Barley water, oatmeal water, rice water														
1	1	9	50	Puddings: Rice, tapioca, bread, custard														
														Total				

directions on the line opposite the apex of the bracket apply to any of the articles included by the arms of the bracket.

It may be found convenient, before filling in the details of the prescription, to write in the column for totals the total quantity of each article to be given in the twenty-four hours, and then distribute that quantity among the different hours of feeding as called for.

After the prescription has been constructed on this blank, the quantities and times of feeding may be copied out in ordinary form, running the eye down the vertical columns to get the articles of food given at each meal or feeding time; and vice versa, dietetic prescriptions which have been constructed in the ordinary form, may be transferred to this blank for convenience in computing their food value.

The food values in the tables are given in "round numbers."

ALCOHOL: ITS STATUS QUO ANTE, NEVER!

By D. NATHAN, M.D.,

NORRISTOWN, PA.

Alcohol, which has come down to us from the remotest of antiquities, will descend soon by crisis into a well deserved obscurity as a beverage. Pharmacological experimentation in *vitro* and *intra vitam*, along with the clinical and pathological evidence which has been available to any physician, have made the therapeutics of alcohol standard, albeit in the hands of *empirics* it has a therapeutic value in all diseases.

Authors need not be quoted as to its action on tissues, liquid, solid, or gaseous. All who have authority to speak are at one as to its effects—deleterious is putting it mild—destructive in the main is its subtle action; its good qualities, if any there be, are as rare as the gates of Thebes.

In no part of the body is the action of alcohol more manifest than in the central nervous system, acting less upon the supporting structure, but more and sooner upon the cells which have evolved the latest and which in dissolution perish first. The inevitable depression following its use makes the user readier for bed than for work. What need we care who is sponsor for prohibition? Whether he be one who has attributed to others his own weakness, whether he be a mattoid, paranoiac or Pharisee—in this case the end has justified the means, and sobriety, against which no one dare argue, is enforced on many who otherwise are a menace to any successful social scheme and a liability to the race. Prohibition, in itself, can hurt no one but the egoistic or self-centered who accumulated hordes of this world's goods by the manufacture or sale of alcohol. Many who would never have voted for prohibition, as it appeared to be undemocratic and to disregard personal liberty, would never think of voting for its repeal. It will take some years to dampen the taste of man for beer, wine, or spirit, but the alcoholic has no more right to indulge such taste than the morphine-eater has to indulge his—two dishes to the one table; only a question of degree, not kind; separate them, though, in favor of morphine whose therapeutic value no one will deny.

The therapeutic worth of alcohol is a debatable one. When I was in Europe some months ago I was told that Sir Victor Horsley wouldn't take alcohol because of his anti-liquor tendencies and on that account he died—he didn't die drunk. As senior medical officer of a transport upon which we had over forty deaths in a few days from the "flu," I tried the only cure (according to some authorities), brandy, and I must confess I never saw one case get better which wouldn't have gotten better without it. When in the tropics some years ago, it was notorious how alcoholics perished and non-alcoholics survived. I was instructed when going to the west coast of Africa: "Leave booze alone and take quinine." Some alcoholics lived but most of them died. There can be no dispute about alcohol's responsibility in the production of insanity; some psychoses may be due to an alcoholic environment in early childhood. I have seen several epileptic fits follow, in epileptics, the taking of a drink—cases in which there had been no fits for many months before. Take notice of the scholar and gentleman under the influence of alcohol—his behavior belies the man as the world wants to see him or nature created him. Many times I have remarked that this or that physician wouldn't enjoy the patronage he does did his patients see him as he was when intoxicated. Alcoholic neuritis will leave us for ever. The steady drinker makes a fearful showing when attacked by acute infectious disease. The tragic, melodramatic, and seriocomic results of its use have been sung by the bards of all nationalities; all strata of society have worshipped Bacchus; but few in their sane moments or a lucid interval recommend the use of alcohol. Its debtors are many of those who fill the jails, insane asylums, and almshouses. The physician, and especially the neurologist, ought to be the last one to champion alcohol. As a body we have long since sung its requiem, and yet there are those who cling affectionately to its use, saying that they require it to cure what the vis medicatrix naturæ can do well without it. Others of the laity who speak for a moderation in its use fail to state definitely what is a moderate amount, making allowance for individual peculiarities. Does not alcohol affect the tissues of one man as it does those of the other, irrespective of his bulk or individual difference in matters of morphology? Some sponges absorb more than others. Who is going to regulate the quantity taken by each person? The psychology of the alcoholic is morbid, at first while under its influence, later because of its effects upon the organs, especially the vascular system, and directly and indirectly upon the central nervous system. It leaves upon all its users a trail of irreparable damage—an everlasting stain. Those who take alcohol as a beverage are alcoholics; it is only a question of degree between the ataxic or reeling, staggering gait, disordered speech, exalted Ego, loss of moral sense of the "drunk" and the increased emotional tone of primary inebriation. Alcohol, *per se*, is not the only cause of crime, insanity, and immorality, but it is one of the most potent factors, and it accounts

for millions of days lost by men who without it will accomplish more and greater things.

If prohibition, as we find it, is not the ideal method of ridding us of such a pest, at least it is a step in the right direction and because of it, in the fullness of time, we can expect a sober nation with all that means. Let us hope that the cachéd supply will soon have run its Godless race, that alcohol be not the prerogative of the rich at any time and that the lawless who traffic in it be dealt with as is their desert. A drug whose abuses are so manifold and whose uses so negligible may well suffer the sentence which has ever been its due.

617 WEST MAIN STREET.

Medicolegal Notes.

Osteopaths Not Entitled to Register Birth and Death Certificates Under Maryland Statute.—The Maryland Court of Appeals holds that osteopaths are not required and entitled to register births and deaths with the local registrar of vital statistics or to furnish him with certificates of births and deaths, under the Maryland statutes which charge physicians with such duties; osteopaths not being physicians. The section of the statute providing that state and municipal officers are not authorized "to accept from any osteopathic practitioner any birth or death certificate," is within the scope of the police power of the state, and must be sustained unless so discriminatory as to be plainly arbitrary and without perceptible relation to the object sought; all reasonable presumptions being in its favor. The court said: "The certificates of birth and death to which the statute refers are required to contain such 'items of information as the state registrar of vital statistics shall deem important or necessary,' in addition to such facts as the date and place of a birth or death, the name, sex and color of a child reported born, the name, age, color, occupation, condition and birthplace of a person reported to have died, the cause of death, duration of illness, and the name and address of the attending physician. It was the evident theory of the Legislature that some of the information which the law directed, or the state registrar of vital statistics might deem necessary, to be included in the birth or death certificates, could be furnished more satisfactorily by a physician having the qualifications demanded by the statute of practitioners of medicine and surgery than by those who were licensed to practice osteopathy exclusively. As to the real necessity for making such a distinction, this court has no right to decide. The only inquiry we are authorized to make is whether the action of the Legislature in restricting the means and agencies by which vital statistics are to be obtained is clearly unreasonable. * * * In our opinion the discrimination we are considering in the present case is not so clearly arbitrary as to justify the court in declaring it void. It relates solely to the collection of vital statistics. The Legislature has the undoubted right to determine as to the methods to be employed in obtaining such information for the use of the public. Its designation of certain agencies for that purpose, in the statute under consideration, is not such an obvious abuse of its discretion as to authorize the court to substitute its own for the legislative judgment and to refuse to recognize the provision as a valid enactment." —Keiningham v. Blake (Md.) 109 Atl. 65.

Physician's Right to Sue Employer for Services Performed at His Request for Employee Not Affected by Workmen's Compensation Act.—A physician's right to resort to the courts to enforce by action his claim against an employer for whom the physician has performed services in caring for an injured employee at the employer's request is not affected by the provision of the Wisconsin Workmen's Compensation Act giving the Industrial Commission exclusive jurisdiction to pass upon the reasonableness of medical bills of the employee. The act deals exclusively with the matters growing out of the relation of employer and employee. Its provisions are binding upon employers and employees electing to be bound by them, and upon no others.

All except employers and employees are strangers to the act, and their usual lawful rights and remedies are unaffected by it. True, it is made the duty of the employer to provide certain medical attention to its employees, but the act does not provide that he who renders such medical services at the request of the employer must submit the reasonableness of his charges in that behalf to the Industrial Commission for its approval and allowance. The physician rendering such services is no more deprived of his right to resort to the courts for the establishment and collection of his claim than though the services had been rendered to the employer personally. The fact that neither employer nor employee, those for whom the act was primarily designed, are affected by its provisions against their consent, coupled with the further consideration that no method is provided by which a physician may consent to be bound by the terms of the act, would strongly negative the inference that the act was intended to have the effect of preventing the physician from suing at law to recover for his services. His remedy in the courts is left unimpaired by the statute, and he may maintain his action therein for the value of his services as he conceives them to be.—Noer v. G. W. Jones Lumber Co., Wisconsin Supreme Court, 175 N. W. 784.

Quarantine Regulations.—The California Court of Appeal, Second District, holds that it may be assumed that under the laws relating to public health, inspection and quarantine may be made of persons upon reasonable ground that the persons so subjected to inspection or quarantine are afflicted with contagious or infectious disease. Where sufficient reasonable cause exists to believe that a person is afflicted with a quarantinable disease, there is no doubt of the right of the health authorities to examine into the case and, in a proper way, determine the fact. But such preliminary investigation must be made without delay, and, if quarantining is found to be justifiable, such quarantine measures may be resorted to only as are reasonably necessary to protect the public health, remembering that the persons so affected are to be treated as patients, and not as criminals.—*Ex parte* Dillon (Cal.) 186 Pac. 170.

Implied Promise to Pay Reasonable Value for Physician's Services.—In the absence of an express agreement as to amount, the law implies a promise to pay for a physician's services as much as they are reasonably and ordinarily worth on the professional market. Where a physician seeks to recover for such services, he has the burden of proving the value thereof.—Huntley v. Geyer, North Dakota Supreme Court, 175 N. W. 619.

Dying Declarations Not Admissible in Civil Cases Before Medical Boards.—It is held that hearsay evidence is inadmissible in a proceeding before the California Board of Medical Examiners to revoke a license ,to practice medicine, under section 14 of the California Medical Practice Act, as amended in 1915, and that dying declarations are not admissible in such a proceeding, or in any other proceeding than criminal cases of homicide.—Thrasher v. Board of Medical Examiners (Cal.) 185 Pac. 1006.

Hospital Records as Evidence.—The Maryland Court of Appeals holds that in a personal injury action a hospital record offered in evidence by a medical witness, not made by the witness, who could not tell by whom it was made, he having found it among other records, is not admissible without further showing.—Zipus v. United Rys. (Md.) 108 Atl. 884.

Testimony as to Physical Condition of Patient Excluded.—In direct examination with respect to her physical condition before the accident, the plaintiff in an action against a common carrier for personal injuries testified that she never had any venereal disease or taint, nor had she taken treatment for any ailment of that sort. It was held competent thereafter for the defendant to offer testimony tending to show that the plaintiff called upon and was examined by a physician, but such physician cannot testify as to the result of his examination.—Livingston v. Omaha & C. B. St. Ry. Co., Nebraska Supreme Court, 175 N. W. 662.

PARENTERAL MILK INJECTIONS.

SOON after Koch had announced his specific treatment for tuberculosis Matthes claimed that the same result could be attained from tuberculin-free albumose. This view, which has since been greatly elaborated, undoubtedly goes much too far, but there is no reason to doubt that alongside of the specific action one of a general character may be seen. As far back as 1893 Rumpf claimed that pyocyaneus vaccine was of benefit in typhoid fever, and numerous similar claims have been made in more recent years. Old tuberculin has been of apparent service in paresis, a gonococcus vaccine in various nonspecific infections, and so on. Finally ordinary horse serum and other nonspecific sera have been used for a variety of infections. Deuteroalbumose and certain commercial peptones have been given, especially in typhoid fever. Milk has also been used, since first recommended by Schmidt in 1916, for a variety of affections, including hemophilia, paresis, chronic arthritis, and infections in general. It has also been used for provoking the Wassermann reaction. A favorable result has been seen in various eye infections and in otitis media, where in some cases the benefit has been startling. Milk injection causes more or less elevation of temperature and leucocytosis. Ryhiner, writing in the *Correspondenz-Blatt für Schweizer Aerzte* some months ago, speaks of the nonspecificity of this form of parenteral protein therapy, and sums up the benefit of the treatment from his own experience. It is, he says, of no apparent value in sterilizing diphtheria carriers or in cases of hemorrhage, anemia, osteomyelitis, sepsis, Barlow's disease, erysipelas, gonorrheal vulvovaginitis, or hemorrhagic nephritis. No reaction follows the injection of milk known to be fresh and sterile. Hence any reaction must be due to the bacteria or other impurities of the fluid. Mother's milk is also devoid of reaction. In repeated injections anaphylactic phenomena have been very rare. This may be due to the protective effect of milk taken per os. Fever and leucocytosis are produced, but no therapeutic effect results. The injections are subcutaneous and the single dose is 0.3 c.c. per kilo of body weight.

Many of these conclusions regarding intramuscular lactotherapy were reached some time ago by Dr. Gerda Uddgren of Stockholm, in a work treating especially of milk injections in the treatment of various diseases of the eye. The book gives the results of this treatment in one hundred cases, including various forms of conjunctivitis, keratitis, iritis, optic nerve disease, and paresis of the extrinsic eye muscles, and also in a number of cases of lupus and of syphilis. The fever, pain, and other outward symptoms seemed to be traceable to the toxins or living bacteria in the milk, but the curative effect is not dependent upon these reactions. The following were the conclusions formulated by Uddgren regarding treatment when practically sterile, nonpasteurized milk was injected: (1) The injection excites a leucocytosis; (2) the general health is usually improved and a gain in weight is observed; (3) in many cases apparently latent syphilis or a provocative Wassermann is noted; (4) tuberculous individuals often respond quickly by a local and general reaction; (6) milk injections have no specific effect, but are therapeutically valuable in provoking absorption and reducing inflammation. Uddgren inclines to Weishardt's theory in explanation of the favorable results of milk injections, namely, that they activate the protoplasm and increase its vitality. She has never seen any anaphylactic shock after repeated injections, though she advises care in the avoidance of such a possibility.

OPERATIVE TREATMENT OF MALIGNANT NEOPLASMS OF THE MAXILLARY SINUS.

THE operative treatment of malignant growths of the maxillary sinus can be effective only if the entire neoplastic mass is removed surrounded by a barrier of healthy tissue. This excision of the tumor *en bloc* is practically possible only in cases where the neoplastic production is still confined to a portion of the sinus. Now, during the period in which these growths are still localized they give rise to no symptoms or at least very few, but there are some warning signs to which value must be attributed. An obstinate suborbital neuralgia without apparent cause and accompanied by anesthesia in the territory of the nerve should invariably excite suspicion. Intractable dental neuralgia which nothing explains, coupled with an expulsive alveolar periostitis is yet another indication of the presence of these tumors. And lastly, very painful and stubborn sinusitis, giving rise to repeated hemorrhage, is almost pathognomonic.

In these cases an exploratory trephining of the antrum is indicated and is to be followed by an histological examination of the neoplastic tissue removed. When the phase of clinical certitude has been reached, much importance is to be attributed to the data obtained by physical means of exploration, diaphanoscopy, and radiography in particular. In the case of a tumor an opening into the antrum will show that the neoplasm is limited to the floor of the sinus, in which case partial resec-

tion of the upper jaw, including the maxillary plate and walls of the sinus, only leaving the roof, is to be done. If the tumor is confined to the nasal wall —ethmoidomaxillary group—a partial excision of the upper jaw is still in order, including a segment of the anterior wall and all the nasal wall of the sinus, the ascending branch, unguis, and the ethmoidal os planum. When the growth is on the roof of the sinus a classical total excision of the upper jaw is indicated. Total excision, with free removal of the surrounding structures, is to be preferred in all cases of malignant growths of the maxillary sinus when they have reached the stage of exteriorization, without, however, placing too much hope on the outcome. Of course the jugular chain of lymph nodes is to be removed, even should they show no evidence of involvement.

In all these operations the protection of the respiratory tract against blood must be assured by Rose's position and plugging of the pharynx after temporary intercricothyroid laryngotomy has been done, but ligature of the external carotid, which has been advocated by some, appears to be unnecessary. There is every advantage in giving a general anesthetic directly by the laryngotomy tube. Among the postoperative measures insufflation of boracic acid in powder and daily irrigations with a borate of sodium solution give excellent results. A prosthesis should be applied, excepting in cases of excision of a growth of the nasal wall of the sinus, in which operation the vault of the hard palate and malar tuberosity are preserved. An immediate prosthesis, which opposes cicatricial contraction, is often preferable to a late one. Finally, the success of the operative treatment of malignant growths of the maxillary sinus depends above all on an early diagnosis, followed by free excision.

CHRONIC TUBERCULOUS ENDOCARDITIS IN CHILDHOOD.

TUBERCULOUS endocarditis is not exceptional in children, and a number of cases have now been recorded. In a recent case published by Nobécourt there was mitral insufficiency—confirmed by radioscopy which also revealed the presence of a mediastinitis as well. There was, in fact, dilatation of the right cardiac cavities, mitral insufficiency, tracheobronchial adenopathy, and mediastinitis in a tuberculous subject who did not offer any stigmata of syphilis or any antecedent infection, but in whom the intradermic reaction was distinctly positive. The case, therefore, was in all probability one of tuberculous endocarditis, anatomically characterized by the usual renal lesions of either simple or ulcerating endocarditis. The last named lesion has been well studied by Braillon, Vaquez, Oettinger, and others. Lesions identical with those of rheumatismal endocarditis usually are seated on the mitral valve and often simultaneously on the tricuspid and aortic valves. They develop at two to three centimeters from the free edges of the valve, presenting a ridge of small, friable, grayish granulations, and are formed by a fibrinous coagulum and vascular and connective tissue trabeculæ coming from the endocardium. No trace of tuberculous follicles can be detected, but Koch's bacilli may be found, while guinea pig inoculation is frequently positive. These lesions have, for that matter, been experimentally produced by Bernard and Salomon.

Besides this secondary endocarditis, the primary lesion has been described by Braillon and is met with in subjects who do not offer the appearance of tuberculous persons; it has the character of simple endocarditis and assumes an acute or subacute evolution. It acts like a local tuberculosis with an attenuated virulence, comparable to tuberculosis of the serous membranes and particularly to that of the pleura. These forms of endocarditis are tuberculous, as is made evident by the presence of Koch's bacillus in the blood of the patients. Clinically this form of endocarditis is marked by rather high fever, lasting for weeks or months, with more or less pronounced remissions, by emaciation, polypnea, dull valvular sounds, and an orificial murmur. Asystolia appears rather early in the process, it is progressive and leads to death. A pericarditis or pleurisy may sometimes develop. These cases of endocarditis, although etiologically specific, are anatomically and clinically commonplace and they do not necessarily terminate in death; they may recover spontaneously, as in a case published some time since by Nobécourt and Dane.

The chronic forms of tuberculous endocarditis must not be overlooked. Braillon has shown that the inflammatory lesions of tuberculous endocarditis have a tendency to undergo an evolution toward cicatrization and sclerosis if their duration is sufficiently long, resulting in the production of thickening, adhesions, and retractions. They can also assume any of the anatomical forms of chronic endocarditis, but at this stage the cicatrices are devoid of any virulence, while bacteriological examination and guinea pig inoculation remain negative.

It is by these processes that not only pure mitral stenosis is produced, but certain mitral and aortic insufficiencies as well. These morbid changes follow primary tuberculous endocarditis, which is frequently latent and curable in so far as it is an acute lesion. Tuberculosis is, consequently, responsible for numerous so-called cryptogenetic valvular cardiopathies in young subjects. A demonstration of this fact is not obtained by the clinical study of the case, but by pathological anatomy as is proven by the coexistence of tracheobronchial adenopathy, mediastinitis, and symphysis of the pericardium. These tuberculous endocarditides, usually marginal and mild, remain localized and are in every way comparable to tuberculous pleurisy or pericarditis.

The treatment appropriate for tuberculosis of the bones is indicated in these cases. An attempt should be made to act directly on the mediastinal process by resorting to radiotherapy, for example. The ordinary general treatment of tuberculosis should be prescribed—rest, fresh air, and judicious feed-

ing. Digitalis is not indicated and its efficiency would hardly be appreciable when asystole had developed.

The "Criminal" Types of Frontal Convolution.

The literature of criminal anthropology contains a number of papers by Lombroso, Benedikt, and others which deal with an alleged splitting of the foot of the second frontal convolution (and to a less extent of the first and third) in those who commit crimes of violence. Pitres and Lande (*Journal de Médecine de Bordeaux*, April 10, 1920, xci, 7) have performed an autopsy on a farmhand who was executed for the crime of rape, pederasty, and suffocation committed on the six-year-old daughter of his employer. The criminal had no bad record, was of fair intelligence, confessed and admitted full responsibility for the crime, showed neither remorse nor fear of consequences, and should by all rights have shown structural abnormalities. There were a few insignificant stigmata of degeneracy, but in general there were no abnormalities found at autopsy, save what was technically termed "incomplete fission of F2." But not only is the anomaly of split frontal convolution found in various types of criminality; it is not uncommon among honest men. Giacomini, who studied the brains of 164 respectable citizens, found incomplete or partial fission of one or another convolution in 47, while in 56 actual criminals the proportion was less instead of greater than the preceding. The anomaly occurs in any of the three frontal convolutions, but is more common in the medial one. The splitting of the convolutions may be said to increase the number of frontal convolutions from three to four or five so that authorities sometimes speak of the "four convolution type" and "five convolution type," according as one or two of the primary convolutions is split. Thus despite the fact that robbers, violators, sadists, and others have repeatedly presented these anomalies, cold statistics tend to negative the significance of such finds.

Is There a Neurotropic Syphilis?

This question is asked and answered by Page in *La Presse Médicale* for April 24, xxviii, 24. The possibility was suggested by Collin in 1914, and in the same year Levaditi and Marie began work on the subject, the results having only recently been published in book form. Their testimony goes far to show that a dualism of the spirochete does exist, although there are clinical facts which do not sustain the view. However, it is possible to harmonize discordant views. Thus the banal spirochete itself may cause a meningoencephalitis, although in most cases this is the work of the neurotropic spirochete. Sanguinetti claims that the banal form causes a special type of cerebral disease in which the arteries are attacked while the "neurotreponema" alone is responsible for the typical paresis, which is an affection of the grey matter of the cortex. The author, for the sake of convenience, calls the banal spirochete the "dermotreponema" because its seat of election is the skin; as already stated it causes only an atypical paresis. The neurotreponema is very benign to the skin and other organs save the cortex, and the subject also on this account escapes proper treatment. Predisposition on the part of the neurons may be a factor. It is possible to foretell the likelihood of meningoencephalitis through early study of lumbar punctuates, and to institute proper and timely treatment.

Martyrdom of Armenian Physicians During the European War.

Vitoux contributes an article on this subject to *La Presse Médicale* for April 17, 1920, xxviii, 23. As is well known the Turks saw in the great war an excellent opportunity to persecute the Armenians to the point of wholesale massacre. The medical men were included, either on general principles or to prevent them from rendering aid to their wounded and suffering countrymen. Since the close of the war the remnants of the medical corps combined in the Armenian Medical Union have made a formal report of the victims. Among the accusers of the Armenians were professors in the University of Constantinople and Turkish army surgeons. All who went before the tribunals were found guilty of some offense and death was the sole penalty. The number of medical men massacred was 67, to which number should be added 54 pharmacists, and 10 dentists. To these should further be added 86 victims of typhus contracted through the responsibility of the accused. The total loss of the Armenian Sanitary Corps was therefore 221 individuals. A number of Greek medical men also suffered the same fate, but that is another story. The extreme barbarity of this persecution is accentuated by the fact that all of these medical men were willing in the interest of humanity to act as surgeons to the Turkish forces and to give their professional services to the civil population.

News of the Week.

Soldiers' Homes as Sanatoria for Disabled Service Men.—Plans are being made for the disbursement of the $48,000,000 appropriated by Congress for the hospital care and medical treatment of disabled ex-service men and the War Risk Insurance Bureau. At a conference recently held between General Wood, president of the board of managers of the National Homes for Disabled Volunteer Soldiers, Dr. Salmon representing the mental hygiene committee of the Rockefeller Foundation; Dr. Pattison representing the National Tuberculosis Association, and Director Cholmeley-Jones of the War Risk Insurance Bureeau, it was decided to convert two of the national homes into sanatoria for the exclusive treatment of tuberculosis and one of the homes into a sanatorium for the exclusive treatment of mental cases. Each of the tuberculosis sanatoria is being equipped to care for 1,000 hospital patients and the sanatorium for the treatment of mental cases will also accommodate 1,000 cases. There are already approximately 17,625 war risk patients in hospitals, of whom 7,980 are in United States Public Health Service hospitals, and 9,645 in hospitals and other institutions not owned or operated by the Government. About 900 hospitals

in the United States are now caring for war risk patients.

Bad Bread or Too Much Bread?—The shortage of American flour for white bread is blamed by the Paris health officials for the sudden increasse in gastric diseases which are filling the hospitals of that city. Professor L'Abbe of the Academy of Medicine, on the other hand, holds that, despite the flour shortage, the bread is better than that which has been obtainable since 1914, and the public is therefore inclined to eat too much of it.

"Ouija" Taken Too Seriously.—Dr. Marcus A. Curry, chief executive officer and medical director of the New Jersey State Hospital at Morris Plains, is quoted as predicting an increase of patients in hospitals for the insane unless the popularity of the ouija board or the present interest in occult and psychic phenomena diminishes soon.

Women Ill After Luncheon.—Physicians are said to be puzzled over the serious illness, with symptoms resembling those of typhoid fever, of thirty-eight women and the milder illness of three score others of two hundred society women of Cleveland, Ohio, following luncheon about a month ago at the home of one of the number. The health commissioner has ordered an examination of samples of food from the catering establishments which supplied the luncheon. A typhoid carrier is believed to have been the source of infection.

Health Record for New York State.—Commissioner R. M. Olive of the Michigan State Health Department has prepared tables from the recently issued Federal Census reports for thirty States, from which it is seen that in preventing death from the seven most costly communicable diseases—typhoid, smallpox, scarlet fever, measles, whooping cough, diphtheria, and tuberculosis—New York State ranked eighteenth in 1918 among the thirty States whose reports are complete enough to be used for comparison. In fighting typhoid and smallpox deaths it ranked seventh; in preventing diphtheria deaths it ranked twenty-sixth.

Increase for Disabled Soldiers.—Under the Darrow bill, which was passed by Congress as a rider on the Deficiency Appropriations Act on June 5, and by the action of the central office of the Federal Board for Vocational Education in approving men in the New York metropolitan district and the city of Buffalo for the fullest benefits under this act, more than 4,000 of the disabled soldiers in training in New York State will receive an increase of twenty dollars per month in their maintenance pay. The base pay for a single man will be $100, while a man with dependents will receive an additional $20 for the support of each. Under the new order the men will receive the increase beginning with July.

New Kind of Endless Chain.—A Chicago doctor recently admitted to the district prohibition officer that because of the endless chain of seekers after whiskey prescriptions he had had time neither to sleep nor to eat. Between February 11 and March 24 he issued 7,435 whiskey prescriptions, an average of 175 a day. He received from fifty cents to two dollars a prescription. On one occasion, he said, he had to call the police to disperse the thirsty mob that gathered about his office.

Monkey Farms Suggested.—Dr. Serge Voronoff, "interstitial gland" fame, who has come to the United States for the purpose, it is stated, of conducting experiments which are forbidden in France, is quoted as urging the establishment in this country of large farms for the breeding of monkeys from which to secure glands for transplantation purposes.

Clinic for Poor Children.—The American Free Milk and Relief for Italy has opened a free clinic and dispensary for poor children of the lower East Side, New York City.

"Movie" of Convalescent Camp Opening.—Moving pictures were scheduled to be taken for distribution throughout the United States on the opening of the convalescent camp for wounded soldiers provided by Mr. C. W. Chapin at Towners, Putnam County, N. Y. It is hoped that the "movie" will stimulate other cities to establish similar camps.

"H. C. L." Strikes Hospitals.—It is announced by the United Hospital Fund that it costs fifty cents a day more to care for each patient in the New York City hospitals than it did one year ago. This is a fifteen per cent increase.

Petition for More Whiskey Blanks Denied by Court.—A practising physician in New York City obtained an order recently requiring Charles R. O'Connor, Federal Prohibition Director for the State of New York, to show cause why he should not issue additional whiskey blanks to the doctor, who claimed that the hundred blanks every three months allowed by the Government was not a sufficient number. When the case came up before Judge John C. Knox in the Federal District Court, the judge held that he had no jurisdiction, and stated that the only way for the doctor to obtain relief was to file a suit in equity and if this warranted it the court could then grant the request. Counsel for the physician said he would follow the suggestion.

Vaccination Urged in New York City.—Dr. Royal S. Copeland, Health Commissioner of New York City, urges that every person who has not been vaccinated against smallpox in the last five or six years be vaccinated at once. This is a part of the campaign of prevention which the Commissioner is instituting with respect to infectious diseases now prevalent in Europe, for the conduct of which the Board of Estimate appropriated $80,000.

Appeal for Nurses.—The New York Health Department, through the Bureau of Child Hygiene, has issued an appeal for nurses. Applicants must be citizens and residents of this State, and they must be registered nurses. The salary after August 20 will be $1,144 a year.

Anthrax Not Always Fatal.—The recent discharge from Bellevue Hospital, as cured, of a well-known polo player who had been treated in that institution for anthrax, has called forth the statement from Dr. Douglas Symmers, Director of the Pathological Laboratories of Bellevue and Allied Hospitals, that a cure is practically certain if begun early. This is the fifth case to be cured in Bellevue with the serum prepared by the United States Department of Animal Industry.

Jewish Memorial Hospital Buys Inwood Prop-

erty.—Announcement has been made of the purchase by the Jewish Memorial Hospital of the Inwood House, an institution for unfortunate mothers and infants. The property, which is situated between 208th Street and the Hudson River Railroad front, will be taken over by the hospital December 1.

"Negro Health Week" in Texas.—The Texas Public Health Association recently conducted a "Negro Health Week" throughout the State.

School for Colored Nurses.—The Piedmont Training School for Colored Nurses, which is conducted as a part of Piedmont Sanitarium, under the auspices of the Virginia State Board of Health, will graduate its first class this month. The nurses will take up the work of combating tuberculosis among negroes.

A New Medical Journal.—*The Medico* is the latest recruit in the ranks of medical journalism. It is edited and published monthly by Dr. Thomas W. Ross of Portland, Ore.

"T. B. Shrapnel."—The South Carolina Tuberculosis Association has issued an official publication under the name *T. B. Shrapnel.* It is to appear monthly, will contain national as well as local data concerning tuberculosis, and will be sent free of charge to anyone desiring copies.

United States Civil Service Examinations.—The United States Civil Service Commission announces examinations, to be held August 24, for Associate in Clinical Psychiatry and Psychotherapy at St. Elizabeth's Hospital, Washington, D. C., at a salary of $2,500 a year and maintenance. Applicants should apply for Form 2118, stating the title of the examination desired, to the Secretary of the Fourth Civil Service District, Washington, D. C., or to the Secretary of the local United States Civil Service Board.

Bacteriologists Wanted.—The United States Civil Service Commission has announced examinations, to be held December 1, for bacteriologist at $130 to $180 a month, associate bacteriologist at $90 to $130 a month, assistant bacteriologist at $70 to $90 a month, junior bacteriologist at $70 and junior bacteriologist, part time, at $30 to $50 a month. Applicants should apply for Form 1312, stating the title of the examination desired, to the Civil Service Commission, Washington, D. C., or to the secretary of the local United States Civil Service Board.

Pharmacologists Needed.—The United States Civil Service Commission announces an examination, to be held August 31, for pharmacologist. A vacancy in the United States Public Health Service, Washington, D. C., at a salary of $3,000 a year, and other vacancies at higher or lower salaries, are to be filled from this examination. Applicants should apply for Form 2118, stating the title of the examination desired, to the Civil Service Commission, Washington, D. C., or to the secretary of the local Civil Service Board.

General Gorgas to Be Buried in Arlington.—The War Department has announced that the body of Major-General William C. Gorgas, who died recently in London, will be buried in Arlington National Cemetery at Washington, D. C.

Sentenced for Manslaughter.—A New York physician, recently found guilty of manslaughter in the first degree in connection with the death of a patient following curettage, has been sentenced to serve from three and a half to fifteen years. Execution of the sentence was delayed until July 26. Judge Louis D. Gibbs, of the Bronx County Court, in passing sentence, denounced "the insidious and uncalled-for propaganda" which had been conducted in the physician's behalf by certain of his colleagues, participation in which was formally denied some time ago by the Bronx Medical Society.

Obituary Notes.—Dr. THEODORE RAYMOND PARKER of Willimantic, Conn., died July 20, at the age of sixty-seven. He was graduated from New York University Medical College in 1880.

Dr. ELIAS LESTER of Seneca Falls, N. Y., died July 18, in his eighty-fourth year.

Dr. HUGH S. KINMOUTH, member of the Asbury Park (N. J.) City Commission, committed suicide at his farm on Shark River, near Belmar, July 21. He was seventy-three years old. Despondency over ill-health is supposed to have caused him to take his life. Dr. Kinmouth was graduated from the College of Physicians and Surgeons, New York City, in 1870, and settled in Asbury Park in 1872. He opened the first pharmacy at Asbury Park, which he continued to run until the time of his death.

Dr. GEORGE F. PITTS of Warwick, N. Y., died July 23 at the age of seventy-one. He was graduated from New York University Medical College in 1877.

Dr. VICTOR PARSONNET, president of the medical staff of Beth Israel Hospital, Newark, N. J., dropped dead recently as he was leaving his home to go to the hospital. Dr. Parsonnet, who was forty-nine years of age, was born in Russia and came to this country when a young man. He was graduated from Long Island College Hospital in 1898 and was a member of the American Medical Association and State and local societies.

Dr. JOHN J. KENNY, who was born on Prince Edward Island thirty-seven years ago, died at Roosevelt Hospital, New York City, July 24. He was graduated from the College of Physicians and Surgeons and was an interne at Roosevelt Hospital. He served for three years as senior medical officer of the Twelfth Regiment, N. Y. N. G., with the rank of Captain.

Correspondence.

THE QUESTION OF COMPULSORY SUBSCRIPTIONS.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR: When a busy practitioner of medicine takes the time to write a letter to a medical journal, and it apparently receives no further consideration than prompt consignment to the waste basket, he undoubtedly must feel both disappointment and vexation, if only for the reason that it requires a greater effort on his part than for one accustomed to writing for the public press and proficient in the use of the typewriter. It is usual when a physician writes a letter to one of the newspapers, that the courtesy of an acknowledgement is accorded him, even though for any reason his letter may not be printed. It is equally discourteous to print a letter with its

errors of the typewriter or of hasty composition uncorrected or even emphasized.

The foregoing has particular reference to a letter of criticism of the *Journal of the American Medical Association* from Dr. Jacob Weiss, which appeared in the July issue of the *New York State Journal of Medicine*, and which undoubtedly was hurriedly written by one but little practised in the use of the typewriter, as evidenced by the typographical errors common to every letter written under like circumstances. It goes without saying that all communications should be properly written, but it likewise is clear that had the editors of the *Journal* been actuated by a proper sense of fairness, they would have either corrected or overlooked these typographical discrepancies and addressed themselves to the question of merit or demerit as affecting the conditions complained of in the letter referred to, instead of evading the issue by merely printing the letter with the obvious purpose of discrediting the writer.

I feel there are many physicians who are in sympathy with Dr. Weiss in the complaint he makes and who will agree that in justice to the members of the medical profession two courses should be open to the fellowship of the American Medical Association, namely, one similar to the present arrangement and the other providing for a membership on the basis of one or two dollars a year without the *Journal*. The members would then be free to elect whether they would or would not take the *Journal*, and the latter would then have to stand or fall according to its own merits.

JOHN D. COGHLAN, M. D.
137 EAST FIFTY-SECOND STREET, NEW YORK.

THE FUNCTIONS OF THE HOSPITAL.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—Your editorial on "The Functions of the Hospital," in the July 10 issue of the MEDICAL RECORD, has impressed me deeply. It is an evidence of the trend of medical opinion on this subject, and I hope will be commented on by other medical journals, so that thoughtful lay periodicals may reverberate their commendation or criticism of this matter.

It is the plan and policy of the new Beth Israel Hospital of New York City to functionate as a medical center for the physicians of the vicinity. The various departments of the hospital will be at their service. They need not bring a patient to a bed in the hospital to have him thoroughly studied. If the patient is ambulatory, he may call to his assistance the various branches of the department of laboratories, the Roentgen-ray expert, the cardiographist, as well as the various clinical chiefs to help him with his "case." For the hospital owes a duty to the community, and must consider all ailing individuals as potential resident patients of the institution, whom it is more economical and more hygienic to cure or help cure in the incipiency of their disease than to wait until the individual is bedridden and must be forthwith brought into the wards.

In certain cases, where the physician desires scientific help at the home of a bed-ridden patient, it should be the function of the hospital staff to place at his disposal assistance, both clinical and laboratory, at the bedside. The hospital should provide itself with portable *x*-ray, etc., should be ready to perform transfusions, etc., if necessary, in the homes of the patient.

The hospital will also be a teaching center for the neighborhood physicians, where they can come and "brush up"; but the hospital will not take upon itself, or duplicate, the duties of the medical society meetings. In these meetings the physicians, if they are attentive, may learn something that is new to them. In most instances the lecturer speaks altogether not like a Demosthenes or a Cicero and his subject is presented in such a hurried and condensed manner that the general practitioner gains little and the specialist—not in the same field—altogether nothing from the lecture. In the hospital, on the contrary, the individual physician will come with his individual query and will be practically given an answer, if possible, to his problem.

The time is passing when a hospital is considered a hotel, with an operating room attached. It is more. It is an operating room, a laboratory, a social service department, a diagnostic clinic for ambulatory and bed-ridden cases, a teaching institution, etc., with bed space conveniences. If this opinion prevails, I believe that the true evolutionary function of the hospital will be realized.

L. J. FRANK,
Superintendent.

OUR LONDON LETTER.

(From Our Own Correspondent.)

LONDON, July 2.

Disease and the Birth Rate Commission.—A matter of considerable interest just now is the presentation of the report to the Minister of Health of the National Birth Rate Commission, which was handed in on June 25 last. The Bishop of Birmingham presented the report and said in part that the war had deprived Great Britain not only of a large number of its male population, but of those of the highest and best quality. It was necessary to take all right measures to restore British citizenship to its normal and even to an improved position. To accomplish that, the marriage of young people in the prime of adult life should be encouraged, but the social state was such that to embark on matrimony was recognized as a rash procedure for those who were not in fairly easy financial circumstances. This was probably most gravely the case among less wealthy people of the middle classes, from whom they might expect the very best type of children. With regard to illegitimacy, the Commission felt that the child must be properly reared and believed that in the vast majority of cases the mother's care would be the best for the child. It was not thought that that would be an encouragement to loose living, but would rather be calculated to inspire a higher idea of existence. The Commission had been met at every step in its inquiry by the painful proofs of the way in which venereal diseases had contributed to sterility, to diseased humanity and to the degradation of the sexual association. The deepest gratitude was felt at the work done by the Royal Commission on Venereal Disease, and it was hoped that it would be possible to find some solution of the debatable

points, especially those in which there would seem to be conflict between the religious judgment of the nation and some advocates of certain methods of safeguarding those who were likely to have immoral sexual relations. The Bishop was persuaded that with sanctified common-sense the apparent differences could be harmonized. Indeed, at the Health Congress at Brussels a few weeks ago, when speaking on this subject, he found that he and Lord Dawson were able to reach almost perfect agreement. He begged Dr. Addison to continue his efforts, as, for the future of the country, it was essential that venereal disease should be throttled. Mrs. John Clay, representing the Mothers' Union, said that more use should be made of women to advise the Ministry of Health. Dr. Addison, the Minister of Health, said that any government must be deeply impressed with the importance of the work under consideration and do what it could to aid it. It touched subjects, however, of a very personal character and people were apt to resent outside interference. The nation was very much indebted to the commission for the valuable work it had done without cost to the state, a particularly good feature in these days, when so much was heard of economy and extravagance. It was an encouragement to know that the birth rate was now rising progressively each quarter and that the effect of the war on the birth rate was to some extent passing off. Mrs. Clay had asked him to seek the help of women to advise the Ministry. In some directions he had anticipated that request, and he was now endeavoring, with the assistance of the Board of Education, to train a supply of well instructed workers. There were on the staff of the Ministry of Health six lady doctors and six midwives, who were aiding them to improve the maternity centres. There was a great need for more maternity homes, and these were now being provided in different parts of the country. The local authorities were also pushing forward the provision of better maternity accommodation. The Ministry of Health had not been backward in research, and in spite of the financial difficulty the government had granted £120,000 for that work. He would consider whether he could make any statement as to policy of the Ministry with regard to the prevention and treatment of venereal disease. The importance of the work done for the prevention and treatment of venereal disease could not be overestimated. It might be that at some centres the work had not been done as efficiently as modern experience showed it could be done, but a number of members of his staff were now devoting themselves exclusively to the increased efficiency of the centres. If the work of the centres was to be really successful and they were to get people to go there promptly they must take every means in their power to ensure that the work was confidential. Certain cases in the courts of law recently had given some misgivings about the confidential nature of the work of medical men. The Ministry of Health was now investigating the position, and he was perfectly certain that, whatever the legal judgment might be, it would be necessary to secure the confidential character of their work, which was essential to the continued success of the campaign against venereal disease.

Medical Men and Secrecy.—At the meeting of delegates to the Congress of the British Medical Association which took place at Cambridge on Friday, June 25, and at which 200 delegates were present, the main matter for discussion was that of the confidential nature of matters which might come to the knowledge of a medical man by reason of his calling. It was moved that, having considered the question of professional secrecy, more particularly with regard to venereal disease, the representative body reiterates the opinion that a medical practitioner should not in any circumstances disclose voluntarily, without the patient's consent, information which he has obtained from that patient in the exercise of his professional duties." Dr. Langdon-Down contended that the medical profession should not shift from the position they had always taken upon this matter —namely, that secrecy should be maintained. There are cases, he said, in which one receives from a court of law an order to divulge professional confidence that is a recognized thing. There are also cases in which the professional man will defy the order of the court and take the consequences. If that is done in a sound case the punishment should not, and will not, be unduly severe. There are also cases when one may feel it one's duty to divulge a secret received in a professional way in order to prevent the commission of crime. The question is, the speaker said, whether the rule would be weakened by satisfying these exceptions. He believed if one began to open the door one took away the great anchor upon which our professional work is based. If there ccurred a breach of confidence between the doctor and the public untold damage would be done, and he thought we should do well to adhere to our old rule of secrecy, leaving the doctor in those cases in which there is doubt and difficulty to decide whether there is compelling reason for him to break his confidence or not. Dr. Sheahan of Portsmouth proposed as an amendment "That the representative body express the opinion that the medical profession should be placed on the same footing as to professional secrecy as clergy, barristers and solicitors, and that the Association take every means to bring this about." Dr. Sheahan contended that a medical man should not disclose any confidence in any circumstances without the consent of his patient. We are supposed, he said, to be state machines without a conscience. There is no reason why we should not maintain our privileges in the same manner as the other learned professions, and retain the dignity, quality, and ancient privileges of our profession. The solicitor to the Association, by request of the members, stated the legal position. He said that so far as the legal profession was concerned, secrecy was not recognized by law, under act of Parliament. So far as secrecy in the Church was concerned, it was on sentimental and not on legal grounds. In America there was an enactment that no doctor should be compelled to disclose any information he may have received in his professional capacity, and in Scotland he found a record of the Court of Session in which it was judicially decided that

secrecy was an essential part of the contract between the medical man and patient. Secrecy had grown up by custom and strong common sense as regarded solicitors. It appeared to him that they would be aiming at almost the impossible in endeavoring to get an Act of Parliament to establish that if a medical man knew that secrecy was going to make a crime possible he would be justified in telling. Dr. J. A. Macdonald of Taunton proposed an amendment to the resolution. "That a medical man should not, without the patient's consent, disclose information unless compelled to do so by a court of law." Dr. Macdonald's amendment was defeated. After discussion the original resolution, redrafted by the solicitor was carried.

State Medical Service.—The Representative Body of the Association, on June 28, was chiefly concerned in discussing matters arising on the interim report dealing with the future provision of medical and allied services issued by the Medical Consultative Council of the Ministry of Health. On a motion that the representative body express a general approval of the report, Dr. C. Buttar, London, proposed a resolution declaring that the Representative Body should define the general principles contained in the report and that those principles be submitted to the divisions for an expression of opinion. Sir James Barr, Liverpool, in seconding, said his estimate was that if the scheme were to be carried out as it should be the cost in the first five years would be 100 million pounds a year and in the next ten years 150 million a year. He had heard it said that this was an ideal scheme, but an ideal scheme must be practical. In his view the State should be entirely engaged not with the treatment of disease but with its prevention. Adenoids was a perfectly preventible disease; pneumonia was also preventible; chronic disease of the heart was also altogether preventable. If one dealt with preventive matters in the proper way, one would not have a consumptive dying before he began to be treated. Dr. Fothergill of Brighton warned the medical profession to be careful, as otherwise they would be jockeyed into a scheme as they were jockeyed into the insurance business some years ago. Lord Dawson said the report only pretended to give the broad outlines of the direction in which the medical profession should move. It was time they asked themselves whether they were going in for individualism or for something of the nature of State action. The scheme might take twenty years to materialize. The medical profession stood higher to-day than ever before in the estimation of the public, who were looking to it for guidance as to the form medical practice in the future should take. Finally, it was resolved that the gathering should consider the general principles contained in the report and that the whole question should be considered at a special representative meeting. A resolution was proposed and carried affirming that the establishment of primary health centers was the pivotal idea of the changes recommended. Dr. Turner, London, proposed a motion , which was carried, reiterating that whole-time salaried State medical service would be detrimental to the best interests of the public and medical profession.

Progress of Medical Science.

1. Specific Aortitis. William D. Reid.
2. Renal Calculus with Negative *X*-Ray Findings. A. Hyman.
3. Observations on the Agglutinating Titre of the Blood Serum in Typhoid Fever. Dwight O'Hara.
4. Prostatectomy (Concluded). Henry G. Bugbee.

2. Renal Calculus with Negative X-Ray Findings.—A. Hyman reports four cases which illustrate the following facts: (1) Negative radiographic findings in renal lithiasis are not infrequent, four such cases being observed within a period of a few months. (2) Latent kidney stones are also not uncommon; in two cases there were no symptoms referable to the side on which calculi were found. (3) The chemical analysis showed urates to be the predominating constituent in all four cases. (4) The passage of a ureteral catheter unobstructed into the pelvis of the kidney does not prove the absence of a ureteral calculus. (5) The wax-tipped bougie is of value; it will every now and then demonstrate the presence of a stone when other means fail. (6) Conservation should be the watchword in all operations upon the kidney. Nephrectomy should be practised as a last resort, for despite negative radiograms and absence of symptoms, the opposite kidney may be the seat of cancerous disease.

4. Prostatectomy.—Henry G. Bugbee, concluding his discussion of this subject (see MEDICAL RECORD, July 24, p. 155), reports an experience covering seventeen years, the first three years, observing and assisting in such prostatectomies as occurred in a general surgical service, and for fourteen years, in operating. His early prostatectomies, performed when the crystallizing stage of the evolution of prostatic surgery was not far advanced, were done by the blind perineal method of intraurethral enucleation. In a four-year experience in this operation, while in charge of an active general surgical service, although there were no deaths, and the operation was looked upon as not difficult, the good results were oversadowed by the few who are now doubtless still going about wearing a urinal and cursing their existence. This was followed by one-stage suprapubic operation, with occasional open perineal prostatectomies, and latterly by an infrequent open perineal operation, but all others by a suprapubic drainage followed by removal of the prostate when the patient's condition warranted. He has had 147 cases, with three deaths, but, incontinence nearly as bad a mortality characterized three of the perineal cases, a perineal fistula persisted in two, constriction of the vesical neck in two, nodules of prostate were left about the vesical neck in two. One death resulted in a one-step suprapubic prostatectomy from hemorrhage when a continuous irrigation was used, one from renal insufficiency, and one of the two-stage cases from uremia. From observation and from results obtained in the two-stage suprapubic prostatectomy, the real grasp one has upon the situation at all times, the possibility of progressing step by step, and the excellent results obtained, lead the writer now to advise prostatectomy in some borderline or early cases in which formerly he would have employed palliative measures. He advises it as a radical cure for a condition which will probably progress, may become malignant, and is a constant menace to the patient, limiting his activities. While he does not advocate one operation for all cases, he believes that the suprapubic two-stage prostatectomy is the safest, is based on the best principles from the anatomical and physiological and pathological standpoints, involves fewer complications, and gives the best functional results of any method of procedure.

8. Treatment of Tuberculosis. Clinical Case Reports (Continued). Benjamin S. Paschall.

5. The Results of Operation in Gastric and Duodenal Ulcers.—George Woolsey bases this paper on a study of the results of operation in gastric and duodenal ulcer in 109 cases, operated on mostly during the last five or six years, up to December, 1919. Acute perforating ulcers are not included. A few of these 109 cases, principally those of gastric ulcer, for which gastroenterostomy or excision was done, date further back, but are included for a comparison of results, as the writer has done relatively few operations of these types in recent years. In the group of gastric ulcer cases treated by gastroenterostomy he included all private records going back to 1902. There are eighteen cases in this group, with no postoperative deaths, making a mortality of 2.6 per cent. for all cases of peptic ulcer in which a gastroenterostomy only was done. The late results in these eighteen cases are known in fourteen, being excellent in eight, satisfactory in three, making 78.5 per cent. of good results. In the three cases marked unsatisfactory one patient when last seen four months after operation, gave an excellent report, but three months later wrote that she was hopelessly sick, without specifying in what way. Another patient was well for eight months when he began to have stomach symptoms at times, especially vomiting, but no gastric pains. He was operated upon again sixteen months after the first operation and the pyloric end of the stomach resected. Since then he has been free from gastric symptoms, but is still neurotic and has a peculiar pallor, though the blood examination is quite satisfactory. The third patient was entirely well for nearly three years, when gastric symptoms, with hematemesis, returned. On resecting the pyloric end of the stomach the stoma, made at the first operation, was found entirely closed, the only case of the kind the writer has encountered. In a group of twenty-six cases of gastric ulcer treated by resection of the stomach four patients died, a mortality of 15.3 per cent. Of the remaining twenty-two patients sixteen have reported the late result. Of these six gave an excellent result, seven a satisfactory, and three an unsatisfactory one, making 81.2 per cent. of good results. In gastric ulcers situated at or near the pyloric end he performs resection, preferably by the Poly-Reichel technic. If the antrum is normal and the ulcer is three to four inches or more proximal to the pylorus he does a mesogastric resection. Where the ulcer is so far from the pylorus as to make this operation quite difficult, an excision, or the Balfour cautery method, with a gastroenterostomy, is preferable. This group includes eight mesogastric resections with no deaths. Only five cases have been heard from and, after reoperation in one case and addition of a gastroenterostomy, the satisfactory results comprise only sixty per cent.

6. Gastrointestinal Disturbances in Affections of the Ocular Mechanism.—L. Winfield Kohn considers it evident from his observations that subjective gastrointestinal complaints often result from eye disturbances, and it would seem that almost any eye disturbance is capable of producing enough irritation to reflexly bring about these complaints, but those most common are anomalies of accommodation, refractive errors and disturbances of the eye movements. It would also seem, here, that a reemphasis of the importance of looking into the question of declination of the meridians of the eyes is indicated. Many eyes are constantly being examined by specialists who seldom look into the condition of the meridians, and as a result a very important factor in the probable creation of reflex disease is overlooked. Many patients, again, owing to the fact that they subjectively experience no trouble with their eyes, often lead the physician away from his path of proper diagnosis. The writer applies the term unconscious ocular disease to this condition in which ocular anomalies give rise to no subjective eye symptoms. Eyestrain, conscious or unconscious, is a rather common condition and by all means requires attention, for through its removal or mitigation the general welfare of the patient can be decidedly improved. Eyestrain so conditions the reflex visceral arcs as to result in the establishment of many untoward body symptoms, and these symptoms often show a predominating relationship to the vagus, hence the condition is spoken of as a vagal neurosis.

3. Post-Salvarsan Jaundice.—Rupert Hallam presents this study for the purpose of calling attention to the prevalence of jaundice occurring during the treatment of syphilis with arsenobenzol preparations, and also to show that it is relatively more frequent with some preparations than with others. He reviews the statistics of other observers and tabulates his own observations in forty-seven cases. With such evidence before one, he concludes, it is necessary to consider whether an infection resembling Weil's disease may not be the excitng factor in the causation of the post-salvarsan jaundice which occurs in what, perhaps, may be termed epidemic form. The grouping of cases has been described by other observers, and although there can be no definitely positive deduction in favor of an infection being responsible for the occurrence, he thinks the possibility is worthy of further consideration. He summarizes his views as follows: (1) That a considerable number of patients suffer from jaundice following the injection of 606. (2)

That it occurs relatively more frequently after the 914 group of arsenobenzol preparations (neosalvarsan, neokharsivan, novarsenobillon, etc.). (3) That it may occur in epidemic form. (4) That the causation is as yet undetermined.

4. Surgery of Congenital Hypertrophic Stenosis of the Pylorus.—Richard Warren holds that most cases of congenital hypertrophic stenosis of the pylorus die if treated medically. Surgical measures, including cases which have become debilitated by overlong expectant treatment, have cured at least 60 per cent., whether by gastrojejunostomy or Ramstedt's operation (Gray and Pirie). Where the diagnosis is reasonably certain from finding a small tumor, presumably the pylorus (with the other signs of pyloric obstruction), operation should be undertaken without delay, and should be regarded as the normal treatment. Where the diagnosis is not absolutely decided medical measures (gastric lavage and small feeds) may be continued for a few days while careful frequent examinations are made for the pyloric tumor. If projectile vomiting persists, feces remain abnormal, or the weight does not increase, a laparotomy should be done high up in the abdomen and the pylorus hooked up through a small incision and examined. Although there is not much difference between the percentage recovery of the cases in the series treated by gastrojejunostomy and the series treated by Ramstedt's operation, the latter will probably be the operation of choice in the future on account of its less severe character. If employed early in all cases the results could probably be considerably improved. There is a great disturbance of metabolism in these infants, rendering the after-treatment a problem in feeding to be solved in each case individually.

1. A Lecture on the Early Symptoms and Diagnosis of Diseases of the Spinal Cord.—Sir F. W. Mott states that the two subjective sensory symptoms which are the earliest evidence of disease of the spinal cord are pain and paresthesia or dysesthesia. They may be the sole symptoms, at first, of severe spinal cord disease, and it should be recognized that a patient who comes to a doctor complaining of localized pain or numbness, tingling, pins and needles, formication, or other abnormal sensations, presents the possibility of early signs of spinal cord disease. Considering the objective disorders or sensibilty, he states that total anesthesia in disease of the spinal cord occurs only in cases where there is a complete transverse lesion, such as occurs in fracture dislocation, bullet wound, or severe meningomyelitis caused by compression or disease; the prognosis is always grave. In meningomyelitis the subjective sensory symptoms and hyperesthesia precede the anesthesia in all cases arising from focal myelitis, or radiculitis, or diffuse myelitis. Dissociated anesthesia is more frequent and more important as a diagnostic sign than total anesthesia in the localization of lesions, by dissociation meaning that all modes of sensation are not affected, or not affected to an equal degree. Superficial sensibility to a light touch with a wisp of cotton-wool, to pricking, and to heat and cold may coexist with unimpaired deep sensibility. An anesthesia to light touch may be associated with the preservation of pain sensibility, and even so exaggerated that touch sensations are only recognizable as painful (anæsthesia dolorosa). This sensory dissociation may be met with in peripheral neuritis and in cases of compression and irritation of roots. In syringomyelia and hematomyelia, where the grey matter is disorganized, pain, heat and cold sensation are not felt, but tactile sensations are. He emphasizes the importance of anatomical diagnosis in prognosis and in cases where surgical interference may be contemplated. It is necessary to decide by examination: First, whether the case is functional or organic. Second, if organic, in order to form a correct judgment regarding prognosis and treatment, it is essential to diagnose the pathological nature of the lesion and its anatomical situation.

2. The Labyrinthine Reactions of Experienced Aviators.—David Ranken presents an investigation undertaken in order to ascertain the difference, if any, between the labyrinthine reactions of experienced pilots and those of the average individual of the same age who has done no flying. From these studies he draws the following conclusions: (1) Experienced pilots have, if anything, a slight tendency toward diminished labyrinthine reactions. (2) Disturbance, present or past, of some other system of the body may affect labyrinthine reactions. (3) Where deafness is present no medical examination of a candidate or pilot is complete without a careful investigation of the functions and reactions of the semicircular canals of both sides. (4) In the absence of a discovery of present or past signs or symptoms pointing to an aural affection, routine examination by means of the Bárány tests is superfluous, provided that a thorough general medical examination is made.

4. Pyelitis et Ureteritis et Cystitis Cystica.—Victor C. Jacobson calls attention to the fact that cystic disease of the renal pelvis and ureter was first recognized by Morgagni, who described the autopsy findings in the bodies of two aged men. No new cases came to light until sixty years later. Johnson, in 1816, reported the case of a female who after pregnancy twice suffered with retention of urine, and in whom the condition was found at autopsy. Following the contribution to the subject by Litten, in 1876, and the report by him of one case, over fifty cases of ureteritis cystica have accumulated, the greater percentage from the experience of European pathologists. Not until 1902 does it appear in American literature, when Harris studied three cases from the Johns Hopkins pathological series. All three were in aged persons, one a woman. Stow, in 1907, added a fourth case, and Hibbs, in 1919, contributed a fifth. Recently Jacobson, in doing routine autopsies at the Peter Bent Brigham Hospital, Boston, encountered three cases in as many weeks. Detailed studies of these cases are given. From this study the following summary is drawn: 1. The condition described is a cystic inflammation of the pelvis, ureters and bladder. 2. It occurs in persons of either sex, in

95 per cent. of cases in senile, arteriosclerotic individuals from whom a history of previous urinary inflammation or other disturbance can be obtained. 3. Three typical cases are reported in detail, all in aged men, two of whom had a history of prostatic trouble and the third bilateral pelvic calculi. In one a double ureter was present. 4. The pathogenesis may be epitomized as follows: (a) In the aged, arteriosclerosis of the ureteral and vesical arteries occurs and is followed by muscular atrophy, fibrous myositis and loss of elastic tissue leading to atony of the ureter and bladder. (b) By the marked infolding of the mucosa which follows, with fibroplasia in the tunica propria, many cell "nests" of Von Brunn are formed. (c) An inflammatory irritant, usually from the pelvis or bladder, causes the formation of granulation tissue which heals over apposed tips of mucosal folds to produce more cell "nests" (this being probably their only source in young individuals). (d) The same irritant produces proliferation of the isolated epithelial cells, followed by central degeneration and fluid transudation, thus giving rise to microscopic and macroscopic cysts. 5. In view of the large number of cell "nests" of Von Brunn in the ureter and bladder of senile individuals and the high incidence of urinary tract infections in the aged, the writer believes that cystic inflammation of these organs is relatively common in this class of patients.

2. The Therapeutic Use of Oxygen.—R. D. Rudolf believes that if oxygen be properly given there is no doubt of its value in suitable cases. He says properly given, for if the administration consists in merely holding a funnel connected with the oxygen tank in front of the patient's face then the results will naturally be *nil*. In this way one cannot raise the oxygen in the alveolar air by more than two per cent., and, further, the patient probably objects to the apparatus, which interferes with his normal breathing. When the oxygen is given by the tube in a nostril great relief can usually be given. During the epidemic of influenza and pneumonia in England last year the writer frequently saw military patients who were breathing badly and cyanosed (even although being treated in the open air) improve visibly in a few minutes under this form of administration. Not only does the cyanosis lessen or disappear and the breathing tend to become slower and deeper, but again and again he heard the patients express their great satisfaction at the relief given, and in such a definite disease as pneumonia the subjective improvement is of much significance and value. In some cases the cyanosis is relieved and yet the breathing remains rapid, while in others the opposite is the case; but in most instances the cyanosis is lessened and the respiration slows. It may be objected that oxygen insufflation is only symptomatic treatment and that the patient will soon relapse, but very often he may not do so for hours or not at all, and the treatment can always be repeated as required. Oxygen should be employed in all serious cases of anoxemia. Its administration should not be delayed and used only as a last resort, but should be employed early, before the vital tissues have been much damaged by the want of oxygen.

La Presse Médicale.

Benign Typhus in France.—Legris, Courcoux and Lermoyez refer only to cases imported during the war. It had been shown that cases not unlike Brill's disease have been seen in Paris before the appearance of the military epidemics, but the authors make no allusion to such cases. The introduction of typhus from infected countries during the latter years of the war has been easy, but apparently in every case the affection was held in check. The danger has somewhat abated, for refugees and imported laborers no longer flock into France, but that danger is still present is shown by an experience last January when a Polish workman was interned in Charity Hospital with headache, prostration and typhoid ensemble. The entire picture was that of marked typhoid of slightly atypical character. The suspicious point was the character of the exanthem which was in several respects unlike the rose spots of typhoid. This broke out all at once like a true rash. There was a pronounced meningeal component but negative lumbar puncture and negative blood culture excluded both typhoid and epidemic meningitis. Inferentially the Widal was also negative. Five similar cases were soon admitted to the clinic and owing to the intensity of the general symptoms and the presence of influenza in the hospital this malady was also considered and excluded. There remained only spotted typhus as a possibility. The patients were all lousy. Certain alleged biological tests employed in typhus countries such as the Weil-Felix reaction and inoculation of a guinea pig with the patient's blood gave negative results. The patients all recovered and in 6 or 8 days after admission were out of danger, although a fortnight more of exhaustion remained. The focus did not extend perhaps, because of the rigorous antilouse measures practised. The diagnosis was not in doubt, and the failure of the laboratory tests was due purely to the advanced stage of the disease on admission, for these tests must be applied at a very early period, otherwise they cannot be relied upon.

Gazette des Hôpitaux.

May 1, 1920, xciii, 41.

Anorectal Gonorrhea.—Barthélemy gives a brief but monographic account of this subject which occurs by preference in females and is not always of infamous origin. Direct autoinoculation is seen in women only, while indirect or mediate autoinoculation is more common in the males. It is related that in 1874 a physician in the interest of science and perhaps very sceptical as to innocent transmission, deliberately conveyed some pus from a gonorrheal ophthalmia into the patient's rectum. The infection took in the anal canal, but the rectum proper escaped. Rollet reported the case of a man who to facilitate his stools was in the habit of dilating the anus with the finger. Having caught a gonorrhea of the urethra he managed to infect himself in the anus with a soiled finger. Transmission by pederasty is less common than should be the case, and appears to indicate that the anorectal canal is much less susceptible than the urethra, conjunctiva, etc. Among women the presence of this malady is no evidence whatever of pederasty and Baer believed that but two cases of 67 women treated were of this etiology. The absence of anorectal stigmata of this vice should decide the question. With men it is the reverse, the presumption being in favor of the vice. The stigmata in question are more apt to be present than absent. In an epidemic of pederasty in a school for boys in which gonorrhea was a complication, only the active participants showed much disease in the form of urethritis. The passives escaped infection. The lesions in anorectal gonorrhea may be very slight so that the presence of the gonococcus must be shown in addition to the presence of stigmata. The latter clearly cannot be produced by isolated acts, however, and should also disappear sooner or later, after abandonment of the vice. Hence diagnosis may be most difficult save in the acute, florid case and in the confirmed addict.

Book Reviews.

CHORIOEPITHELIOMA MALIGNUM. Kliniske og Pathologisk Anatomiske Studier. Med Bidrag til Belysning av Blaeremolaens Overgang til Chorioepitheliom. Summary in English by ANTON SUNDE. Kristiania: Emil Moestue a/s Boktrykkeri, 1920.

THIS volume is made up largely of 38 personal case histories of chorioepithelioma with a tabulation of 122 cases of vesicular mole, but 6 of which appear to have undergone malignant degeneration. The author shows that chorioepithelioma is by no means so fatal as is commonly taught, for of his 38 cases 12 are known to have remained free from relapse after operation for a period of from 3¼ to 15 years. The total number of cases of vesicular mole controlled is much larger than the tabulation, amounting to 240 cases. The book is almost wholly personal and the material came from the local Rikshospital and other Scandinavian clinics.

CUNNINGHAM'S MANUAL OF PRACTICAL ANATOMY. Revised and Edited by ARTHUR ROBINSON, Professor of Anatomy in the University of Edinburgh. Seventh Edition. Volume First. Superior Extremity; Inferior Extremity. With 203 illustrations, many of which are colored. New York: William Wood & Company; Edinburgh, Glasgow, and London: Henry Frowde and Hodder & Stoughton, 1919.

CUNNINGHAM'S Practical Anatomy is so well known that it is hardly necessary to say more than that a new edition has appeared. The text shows a few changes, and many new illustrations have been inserted. The work now appears in three volumes, instead of in two, as heretofore. For the benefit of any readers who may not be acquainted with this book, it may be well to say that it is not a mere dissection guide, nor is it a textbook on anatomy; but it includes almost all the anatomy that a physician is likely to want to know or to need to make use of in the course of his professional work.

PIONEERS OF BIRTH CONTROL IN ENGLAND AND AMERICA. By VICTOR ROBINSON, Ph.C., M.D., Author of Pathfinders in Medicine, The Don Quixote of Psychiatry, etc. Formerly Editor of the *Medical Review of Reviews*. New York: Voluntary Parenthood League, 1919.

THIS little book—it is scarcely more than a pamphlet—contains a summary of the various steps in the Birth Control movement from the time of Malthus to the present day. Among the advocates of the movement will be found the names of Malthus, James Mill, John Stuart Mill, Bradlaugh, Annie Besant, and A. Jacobi. The book, though slight and sketchy, makes easy reading, and contains illustrations of some of the more prominent among those who have written on behalf of Birth Control.

DISEASES OF NUTRITION AND INFANT FEEDING. By JOHN LOVETT MORSE, A.M., M.D., Professor of Pediatrics, Harvard Medical School; Visiting Physician at the Children's Hospital; Consulting Physician at the Infants' Hospital and the Floating Hospital, Boston; and FRITZ B. TALBOT, A.B., M.D., Instructor in Pediatrics, Harvard Medical School; Chief of Children's Medical Department, Massachusetts General Hospital; Physician to Children, Charitable Eye and Ear Infirmary; Consulting Physician at the Lying-In Hospital and at the Floating Hospital, Boston. Second Edition, Revised. New York: The Macmillan Company, 1920.

THE second edition of this work shows little change from the first. The scope of the work remains the same. It is intended to give modern views on physiology, the digestion and metabolism of fat, carbohydrate and protein. The influence of salts on the metabolic process forms an interesting chapter. There are many pages of bacteriology and chemistry which are well adapted for the chemist; so for instance on page 213 the polycarbohydrates are discussed. Caloric studies are included in the chapter on energy metabolism. The bacteriology of the gastrointestinal canal and stools forms also a small part of the book.

A debatable question is whether or no the heating of milk, the steaming of milk, or the boiling of milk gives best results. These authors advise the cooking of milk. They state: "Granting that cooking of milk does make it somewhat less digestible and that its continued use does predispose to the development of the diseases of nutrition, it is evident, nevertheless, that the disturbances which it causes are slight and insignificant in comparison with the diseases caused by milk contaminated with bacteria. All milk except the cleanest should therefore be cooked before being used as a food for infants." In the following paragraph we find the statement, "The higher the temperature at which milk is heated, the greater are the changes in its composition. * * * Pasteurization is therefore preferable to boiling. Clinical experience supported by abundance of literature warns against the indiscriminate boiling of milk because the antiscorbutic factor is destroyed and because rachitis and scurvy are more often encountered after the use of boiled milk than otherwise.

PERSONAL BEAUTY AND RACIAL BETTERMENT. By KNIGHT DUNLAP, Professor of Experimental Psychology in the Johns Hopkins University. St. Louis: C. V. Mosby Company, 1920.

THIS essay consists of two parts; the first deals with the significance of beauty, and the second with the conservation of beauty. The former part was originally delivered as an address before various gatherings, and was published in the *Psychological Review*. The second part appears, presumably, for the first time. The author states his views with little or no argument; indeed, as the views expressed are those generally accepted, no argument is needed. The book may serve as an introduction to the study of eugenics and other sociological problems of the day.

GRUNDRISS DER PHYSIOLOGIE für Studierende und Ärzte. Erster Teil, Zweite Auflage, Biochemie von Prof. CARL OPPENHEIMER, Dr. phil. et med., München. Zweiter Teil, Biophysik von Prof. Dr. OTTO WEISS, Dir. des physiol. Instituts Konigsberg i. Pr. Leipzig: Georg Thieme, 1919.

THIS work appears in two volumes, of which the first is in its second edition. The first part might be called physiological chemistry, and contains a fairly complete presentation of the subject. There is nothing strikingly new, either in the material or the manner of its presentation. Secretions and excretions are given comparatively little space, and the bulk of the volume is devoted to the chemical aspect of metabolism. The second part, under the title of biophysics, corresponds more nearly to the ordinary physiology with the chemistry left out. Physiology of the nervous system, of the general subject of movement and of the organs of special sense form the chief part of the work, and but little outside of these receives consideration. The physics of the eye are discussed in detail, and there are some fifteen pages devoted to the mathematical aspects of refraction. The work as a whole contains much that is valuable, and is well written, but the divisions do not correspond to courses as they are given in the schools in this country. While the first would do fairly well in a course in physiological chemistry, the second would be inadequate for a course in physiology unless supplemented by other works. Neither would be considered as satisfactory substitutes for standard works which have appeared in this country.

ANLEITUNG ZUR FUNKTIONSPRÜFUNG DES OHRES (Prüfung des Gehör—und Gleichgewichts—apparates). Von Dr. A. SONNTAG und Dr. H. J. WOLFF, Zweite verbesserte Auflage. Berlin: S. Kurger, 1920.

THE first edition of this work appeared in 1912, and before the declaration of war in 1914 a revision was already in progress which was naturally much delayed in consequence. The first section on tests for hearing remains unchanged, but the section on the equilibrium apparatus has been completely rewritten and the article on tests of the cerebellar functions is quite new. The present edition is made up of 76 pages, with 23 illustrations. A singular omission is the absence of any allusion to tests of the labyrinth for aviators which forces the belief that the book is essentially an *antebellum* affair.

Society Reports.

MEDICAL SOCIETY IN THE COUNTY OF NEW YORK.

Stated Meeting, Held May 23, 1920.

THE PRESIDENT, DR. CHARLES H. CHETWOOD, IN THE CHAIR.

THE program of the evening was contributed by the American Society for the Control of Cancer.

The Relation of the Medical Profession to the Campaign for the Control of Cancer.—Dr. ROBERT B. GREENOUGH of the Harvard Cancer Commission, Boston, Mass., delivered this address. He said, in part, that the last ten years had brought many new duties and responsibilities to the medical profession in the way of public service. In connection with the control of cancer the responsibility which had come to the medical profession brought also a great opportunity. Statisticians told us that there were from 80,000 to 100,000 deaths from cancer in the United States each year and that it was one of the most common causes of death of persons over forty years of age. There was no cure except by radical surgical operation, and a relatively large proportion of cases presented themselves for treatment too late to be cured. At the Massachusetts General Hospital of 519 cases of all varieties of cancer entered as operable only 44 per cent. were suitable for cure by radical surgical operation. The operative mortality further increased the mortality rate so that only 38 per cent. stood a chance of radical cure. The expectation of failure in operation on cancer in certain regions of the body was greater than the hope of success. There was no question as to the duty to endeavor to gain control of the cancer situation. As a means of accomplishing this the public must first be educated to recognize the early symptoms of cancer; the medical profession must be instructed as to the absolute facts in connection with cancer; there must be a knowledge and promotion of the best methods of treating cancer, and laboratory work must be carried on in the effort of finding methods other than surgical for the treatment of cancer. During the last ten years the attitude of the public had changed greatly toward public health matters as a result of the work of the many agencies that had undertaken to educate the public for its own good. As evidence of the recognition of the importance of public health work might be noted that many subjects not formerly mentioned were now discussed by the lay press. Public health propaganda was being spread by many agencies, the newspapers, magazines, pamphlets, lectures, etc. The facts in reference to cancer that had to be impressed upon the public mind were few and simple. The facts that had to be taught were that delay was dangerous; that it was the early and not the late case that was cured by operation, and that early operation could and did cure many early cases. The public should be taught that pain does not occur with cancer in its early stages, and that any lump that was painless, especially if it bleed, was suspicious and should be investigated. Much had been done to teach the public these facts, but much more remained to be done before the work was finished. Articles in the newspapers and magazines might arouse the interest of a patient but it was to his own physician that he turned for definite information. In their series of 519 cases there was a delay of 5.4 months after the growth was noted before a physician was consulted. That was far too long in any case for the best interests of the patient. The patient must be induced to consult his physician earlier if the disease was to be combatted successfully. The figures did not indicate that much progress had been made as yet in checking this disease. By instructing the public they hoped to bring the cancer patient earlier to the physician, but this added to the responsibility of the physician. If he wished to secure to the patient the opportunity for cure to which he was entitled we must abandon the textbook description of cancer, which described the disease in its well established form, and teach the earlier symptoms. No sense of false modesty on the part of the patient and no indifference on the part of the physician should be allowed to interfere with a thorough and proper examination. A Fabian policy of delay in many cases meant death. An average delay of three months occurred in their series of 519 cases after the patient consulted a physician before the patient was presented for operation. An investigation showed that as a rule the patients had presented themselves for operation almost immediately after they were advised by their physicians to do so. This average delay of three months was far too long in a disease that progressed as rapidly as cancer did at this stage. With reference to the removal of tissue for pathological examination, the trend of opinion was opposed to this procedure. This risk varied with the location of the tumor; there were some tumors that could not be diagnosed in any other way. The frozen section with immediate microscopical examination was the method generally approved. Conditions termed precancerous, such as keratoma, papillomata, leucoplakia, lacerated cervix, pigmented moles, etc., conditions which were known in many instances to have developed into cancer, should be removed by surgical methods. This served as prophylaxis against cancer and permitted microscopical examination of the tissue removed. If for any reason it was not expedient to remove these pre-cancerous conditions they should be treated with radium or the *x*-ray. If these agents were used it should be by one radical exposure, inasmuch as small doses might be merely irritating, and since it was acceded that chronic irritation might give rise to cancer. The surgical teaching of wide excision in all cancerous growths was universally accepted, and standard operative procedures for cancer located in various parts of the body had been collected by the Society for the Control of Cancer, published in pamphlet form, and issued to state health boards which distributed them to every physician. The prospect of recovery in a case of cancer was determined by the anatomical situation of the growth because it was this which limited the amount of tissue that could be excised. It was to be hoped that in the future surgeons would be enabled to remove cancer from locations which had not been open to attack thus far. The development of combined treatment by operation and radium was an advance that must be accepted. While there were many problems in connection with research work in cancer that had not been brought to solution, it had been shown by experimental work in the transplanted tumors of mice that there were certain dangers connected with *x*-ray and radium treatment. Experimental confirmation had been obtained showing that rough handling hastened the spread of cancer and that a clean incision was the safest method of making a diagnosis where it was otherwise unobtainable. Cancer research institutions and other institutions and individuals had from time to time proposed methods, some biological and some chemical, supposed to cure cancer, and while none of these had thus far proven successful it was the duty of cancer institutions to continue the search for any remedy that held out promise. Radium and the *x*-ray were of the greatest value and a place in the treatment of cancer had been found for each of them, and in those places they were productive of the greatest good. In closing, Dr. Greenough said that in this communication he had tried to show that the situation at present was very serious; that it demanded the best there was of all the medical profession towards its relief; that more should be done to help the physician recognize the disease in its early stages; that we must teach that the precancerous disease justified and demanded treatment as a prophylactic measure, and that they should encourage investigation on the part of laboratories all over the world with the aim of improving the treatment of this insidious disease.

The Aims and Methods of Cancer Diagnosis.—Dr. JAMES EWING presented this contribution in which he said that it was not necessary to wait for the results of cancer research to suggest methods for the early diagnosis and control of cancer. The medical profession was occupied with cancer when, for instance, there was a lump in the breast and several in the axilla and the patient had the very obvious symp-

toms of the disease. When a woman had a palpable lump in her breast and enlarged axillary glands she had one chance in twenty-five of being cured. In cancer of the uterus, when there were a discharge, pain, and local discomfort, cancer was well established and the chances of recovery were very slight. In the stomach, if there was a palpable tumor and the symptoms indicated that the cancer had surrounded the pylorus and ulcerated, the chances of cure by any method available at the present time was so slight that it was not necessary to speak of them before an audience of medical men. Cancer in these three situations constituted over 70 per cent. of all types of cancer. Looked at from the point of view of statistics, it was estimated that 85,000 to 90,000 deaths occurred in the United States annually from these three groups of cases. All statisticians were convinced that there was a steady and alarming increase in the incidence of cancer. From the statistical standpoint the medical profession was not making much impression so far as the problem was concerned. In spite of improved methods of diagnosis and treatment as many persons appeared to die of cancer as before and the reason was that the diagnosis was not made early enough and the physician was dealing with the disease after it had reached a stage when there was no hope. At the present time the surgical treatment of cancer was not of much economic importance. In view of these facts the representatives of actuarial societies had established a national organization to bring about a greater knowledge of cancer and of its early diagnosis, and that was also the object of the American Society for the Control of Cancer. It was most important at the beginning of this movement to increase our knowledge of cancer vastly beyond anything thus far attempted. There was a tendency to slur over cancer and speak of it as malignancy, and to assume that if once malignancy was established it was then the part of the surgeon to remove the growth. That was a very incompetent point of view, because cancer in different parts of the body differed enormously. There were certain rapid-growing cancers that could not be tampered with, while, on the other hand, there were slow-growing types of cancer that ran along for years. In order to distinguish these types the physician must demand much more accurate knowledge than was commonly possessed today. It was not sufficient to recognize malignancy; it was necessary in addition to determine the type of cancer and the course that type of malignancy ran. For instance, an innocent-looking mole on the toe might excite no particular attention until nodes appeared in the groin. By the time the character of the condition was recognized the physician realized that he was face to face with a fatal disease. In many instances the total duration of this type of cancer was twelve months; in a few cases it might be two or three years, but the prognosis was always fatal. A rodent ulcer on the other hand, might begin on the nose as a small scale or scab, which every time it was removed re-formed. The physician might tell such a patient that the lesion was a trival one. Later the patient might drift into the hands of a quack who applied a little nitrate of silver. After this the patient might appear to improve a little, and would go along for perhaps five or six years when the condition would become more serious and a surgeon would excise the ulcer. In the course of ten years the lesion would have become really serious, and by the fourteenth year nerves, bones and blood vessels would be involved. Twenty years might elapse in such a case between the beginning of the lesion and the fatal termination. In the breast an acute carcinomatosis might prove fatal in three or four months, while there was a type of cancer of the breast occurring in elderly women that might run along for twenty-five years, and death might occur from some other cause. Unless a physician was able to differentiate between different types of cancer in different parts of the body and different types occurring in the same organ, he was unable to deal efficiently with them. Mammary cancer had attracted more attention than any other form of cancer and its treatment had been less satisfactory than that of any other type. Dr. Ewing said he had found the statement in the literature made by an old English pathologist that mammary cancer did not arise from the gland tissue but from abberrant sweat glands. Experience had shown that this statement was correct, and it was conceivable that this information might prove useful. Certain types of sarcoma in the long bones, occurring usually in younger subjects, was most destructive and often caused the sacrifice of life and limb. On the other hand so-called benign was often mistaken for giant-celled sarcoma and limb unnecessarily sacrificed. The subject of tumors of the long bones was in almost complete chaos. Instead of the term benign sarcoma it might be advisable to substitute the term hemorrhagic osteomyelitis, for certainly the condition was benign and did not require amputation. The majority of cases of giant-celled sarcoma, if submitted to *x*-ray examination at the time of operation would show metastases in the lungs. Then there were tumors from the blood vessels of the long bones that were difficult to distinguish from ordinary myeloma. Before we could hope to deal successfully with tumors of the long bones we would have to learn to differentiate between the various types. Again, considering tumors of the peripheral nerve trunks, VonRecklinghausen's disease affected the whole neural ectoderm, with all sorts of peripheral, cutaneous neurofibromatoses. Over against this condition subcutaneous neurofibroma, a painful, hard, elastic tumor under the skin. If a tumor of this kind occurred in a limb and was excised it was likely to recur higher up. In one case coming under his observations this had occurred repeatedly until twenty-two operations were performed in the course of a few years, yet no one had told that patient that his conditions was serious. In neurosarcoma of the skin unless the physician knew more about the changes that were going on than he generally knew he was incompetent to recognize them in the early stage or to deal with them in any stage. In speaking of precancerous lesions, Dr. Ewing said he agreed with everything Dr. Greenough had said. He recalled having heard discussions on this subject in which it was declared that there was no such thing as a precancerous lesion—that a disease was either cancer or it was not a cancer, that cancer sprang into being full-fledged. As a matter of fact there were certain diseases capable of producing changes which were followed by cancer. For instance, lupus vulgaris was followed by epithelioma of the skin in 30 per cent. of the cases, not immediately but at the end of twenty-five or thirty years. If during this period one examined the lesion no trace of cancer could be found, so that it could not be assumed that there was anything essentially cancerous about lupus vulgaris. Histologically and clinically syphillis of the tongue was often followed by cancer, so that we had a right to consider it a precancerous condition. Excessively pigmented and atrophic skin and rodent ulcer developed into precancerous lesions which misroscopically might show some of the histological features of beginning cancer. Lesions in this precancerous stage could be removed by slight operations, or they might be cured by radium and the *x*-ray, though he would not recommend these agents. The diagnosis of cancer by serum methods was, in the speaker's opinion, of no definite value, and was at best on a very unstable theoretical basis. He based more faith on clinical methods, carefully applied by a skillful person than on other means of diagnosis at the present time. It was a strange fact that the clinician always insisted that laboratory methods be applied to diagnosis, while the laboratory worker favored clinical methods, palpation, inspection, and observation over a period of time. He had spent a great deal of time in the laboratory and preferred to base his diagnosis upon careful clinical methods. There was, he supposed, a common ground where laboratory worker and clinician would some day meet. While he would not depreciate the accuracy of biopsy, he thought that where a tumor was visible to the eye it permitted of diagnosis and the surgeon should not wait for the laboratory to come to his help, but should make the diagnosis on his own responsibility. A physician did not impress other physicians or the public by his knowledge of cancer by applying a blanket rule to all breast tumors and insisting that every lump in the breast be excised. In distinguishing between

malignant and benign tumors of the breast it was important to take into consideration the age of the patient, location of the tumor in the breast, the consistency of the tumor, the history of the organ, and all features of the case, and in that way one could usually reach the diagnosis. The failure to recognize cancer was often due to lack of proper physical examination. It was estimated that 70 per cent. of rectal cancers were treated first as piles. At the Memorial Hospital they were surprised at the frequency with which the presence of a positive Wassermann reaction led to the treatment of a cancerous condition with salvarsan, mercury, or the iodides. A physician should not be deceived into the idea that cancer could not coexist with syphilis. As to the frozen section, he felt that this idea was being badly overworked. Unless the pathologist was a good enough diagnostician to pick out a cancerous nodule, it might easily be overlooked, and the examination of a frozen section then availed nothing. If, on the other hand, the pathologist was a good enough diagnostician to pick out cancer in the gross then the microscopical examination was unnecessary. Every surgeon who undertook to deal with cancer should familarize himself with the gross characteristics of cancer so that a frozen section would be unnecessary. The whole question of cancer control reduced itself to one of medical education. Unless students were turned out from the medical colleges with a knowledge of the scope of this problem, and were acquainted with the early signs of cancer they would be more or less incompetent and negligent. He believed the medical school had the largest responsibility for the future control of cancer and the largest accountability for present negligence. In the undergraduate curriculum students should be taught much more than they were taught to-day, and until that time came the American Control Society would not have results fully satisfactory.

Dr. JOHN P. DAVIN congratulated Dr. Greenough and Dr. Ewing and said that Dr. Ewing had emphasized the right point in his postscript when he spoke of medical education and of the responsibility of the medical schools. The ignorance of physicians about things they should know was appalling. Some one had said that the bill posters put out in connection with this campaign were a reflection on civilization. Before the medical profession gave support to a publicity campaign it should look to its own knowledge on this subject. The great accomplishments of the medical profession had been effected without money or advertising and he thought this would be true of its achievements in the future. With the education of the medical man the people would follow his advice.

Dr. BOLESLAW LAPOWSKI said that in the present state of our knowledge it was impossible to make a definite correct diagnosis of beginning carcinoma upon the tongue. Unless one excised every suspicious lesion he was liable to make mistakes. Neither could the pathologist help the clinician in many doubtful cases, especially in lesions of the tongue in syphilitic patients. Even in advanced cases of the disease, it was not always possible to make a definite differential diagnosis between carcinoma and syphilis and the position of the clinician as regards the treatment in such cases was a very trying one. One could not force mercurial treatment, owing to the fear of increasing the amount of salivation, which was always in a more or less degree present and undesirable in such cases. Even salvarsan did not give good results and the opinion of a good many clinicians was against the use of iodide of potassium in such cases, and thus the hands of the clinician were tied. No lasting results could be obtained in such cases from surgical interference.

COMMANDER WILLIAM SEAMAN BAINBRIDGE said he was sure he voiced the unanimous appreciation of all those who had heard the two splendid papers read before the Association. There was such valuable material and so much of interest in them that he was anxious to go over the papers again when they were published. Frequently one's own experience pressed home facts more forcibly than anything else could do, and his experience recently in several cases of cancer had brought home some important points with special emphasis. A few months ago a boy fifteen years of age who had enlisted in the naval service eight months previously was attached to the receiving ship at New York. The boy had had for over a year a small spot on the dorsum of the base of the second toe which was supposed to have been caused by pressure against a shoe. It had remained about the size of the tip of the little finger; there was no change in color, and it caused no symptoms. A week before he entered the Brooklyn Naval Hospital he stubbed his toe, and there appeared to be an acute inflammation starting three days before his entrance to the hospital. At the dispensary the mass was incised, as it was believed to be cellulitis. No pus was found. Three days later he was brought to the hospital and a diagnosis made of probable sarcoma. With a red hot cautery the mass was removed and sent to the laboratory. The laboratory diagnosis confirmed the clinical diagnosis. Further operation was refused at the time. Three weeks later there were enlarged glands in the groin on the same side and rapid extension took place into the abdomen and other parts of the body; three months later he died of general sarcomatosis. It would seem from the history and conditions found in this case that at the time the incision was made into the growth there was no evidence of any trouble higher up, and three days later, when the cautery was used to remove the entire mass and block off the extension was the time when the sarcomatous cells had already passed upward. The second case was that of a young man, twenty-six years old, a sailor, who had had a pigmented mole on his back for many years. This was irritated and the area became somewhat indurated. The nodule was removed; it was about the size of the end of the finger and proved to be melanotic sarcoma. Inside of six months the man was unable to get out of bed, the extension had been so rapid starting a few days after the surgical operation. The man was still alive, but his death was only a question of a very short time, as the disease was practically universal throughout the body. Another point which he was very glad to hear Dr. Ewing emphasize was the importance of not being too radical in relation to every lump in the breast. We had a period of the massacre of the ovary, then the massacre of the appendix, the tonsils, and more lately the teeth. Now it seemed that the dictum of some was that every woman with a tumor in her breast should have the tumor or the breast removed within forty-eight hours after it is discovered. This, he believed, in many cases was altogether too radical. We should demand of the public that they come to us early, but we should demand of ourselves and the students that came after us a sounder knowledge and especially a better ability to make a well poised diagnosis.

Dr. GEDIDE A. FRIEDMAN called attention to the fact that in carcinoma of the stomach or intestine the services of a pathologist were not needed; a diagnosis could be made without the pathologist and the same was true of cancer of the esophagus. Some again spoke of the value of the *x*-ray in diagnosis. The *x*-ray was very good and would make the diagnosis when the condition was well developed, but in early diagnosis the *x*-ray was of no use. The clinician was the man who made the early diagnosis of carcinoma of the stomach. Dr. Friedman cited a case coming under his observation several years ago, in which carcinoma of the sigmoid was suspected. The patient was proctoscoped and a specimen of a small growth in the rectum taken and sent to the laboratory for examination. The report came back carcinoma. The man was opened and nothing found. Later on another proctoscopic examination was made and a growth found in the rectum and cut out. It was found to be a benign polyp. The man came under observation three years later with symptoms pointing to the stomach. A diagnosis of ulcer of the stomach was made and the man operated upon. The pathological report was carcinoma of the stomach. Dr. Friedman said he did not understand this case. The question suggested itself whether the condition previous to finding the carcinoma of the stomach was a precancerous stage, or whether a mistake was made in the pathological examination. As Dr. Ewing had pointed out the surgeon should familiarize himself with the gross pathology of carcinoma and then he would recognize carcinoma in those organs which were accessible to inspection.

Dr. EDWARD WALLACE LEE said that when he came to the meeting this evening he felt very confident of his knowledge of neoplasms of malignant character, but when he came to a medical meeting he always had someome tell him something altogether different from what he had learned before, so he often went away from a meeting very much discouraged. The one point impressed upon him was that the medical profession should be taught because they were constantly making errors in diagnosis. When he looked back thirty-five years he could remember having told a woman that she should have her breast removed because it had a lump in it, and today that breast gave her no trouble. In another case he could recall having said that lump was only a little cyst and could be opened, and the woman had followed that advice and had died from cancer. How was one to know what to do?

Dr. EDEN V. DELPHEY said that in his school days the Latin fables always ended with "Hæc fabula docet." What these papers taught were not fables but facts and the teaching was very applicable to the present time in the endeavor to control the ravages of cancer. Cancer should be diagnosed and operated on early, and the way to do this was to educate the public to go to the physician as soon as any abnormal lump presented itself or any other abnormal condition was manifest, and then to do just exactly as the physician directed; to educate the physician to make a true and just diagnosis of the condition when presented and then to send the patient to the surgeon as soon as possible if the condition were cancer. Most unfortunately according to the papers presented tonight the condition was present for 5.4 months before the patients went to the physician and were therefore frequently hopeless at the time of diagnosis, even though some palliative operation might be done which would make the patient more comfortable and perhaps lengthen his life. Sometimes the physician waited before advising operation, being influenced by the results of former experiences in sending the patients to the surgeon. He, himself, had sent a patient to a surgeon for operation for a carcinoma encircling the left ureter immediately on making the diagnosis; the surgeon had made a very extensive extirpation of the neoplasm, the operation lasting two hours and fifty minutes, and the patient promptly died two hours later from shock. Not only did he lose the patient but he lost all her friends and relatives. Although such an experience would not deter him from sending patients for operation, he could very easily see how others might consider that the patient might live longer without than with an operation. In another case, a young woman 35 years of age, with a small lump in the breast, he watched it for six months and although it had not increased in size, he advised its removal. The patient refused and now it had disappeared. This latter was evidently a benign tumor. To recapitulate: We must educate the public to go to the physician early and to do as he advised; we must educate the physician to make a diagnosis and send the patient to the surgeon early; and we must educate the surgeon when to cut, when not to cut, how much to cut, and when to stop cutting in order to get the best results for the life and comfort of the patient.

Dr. LOUIS FAUGERES BISHOP said that it seemed to him that the gist of public health education and public health inspection, and the drift of medical economics and public health economics was toward the periodical physical examination of the whole population. That was what would relieve us of the futile attempts to make people submit to examination to detect cancer or any other one disease. Periodical physical examinations would serve not only to reveal carcinoma, but cardiovascular disease as well, which was equally fatal with cancer and which was much more preventable.

Dr. GREENOUGH said that he quite agreed also that instruction should be given in our medical schools on the early diagnosis and other problems connected with cancer, but it would be a mistake to wait for that to bring about the desired result, because it would be ten or fifteen years before the men in medical schools today would be doing the work that the practitioners of medicine were doing now. In regard to biopsy, there was no doubt that surgeons as a class were opposed to cutting into cancer tissue, yet a surgeon hesitated to remove a whole tongue or perform some other very serious operation without a pathologist's report. It must be admitted that the problem was going to be made more difficult by bringing the patient early to the physician, and it must also be admitted that the surgeon needed further resources, and that there would be cases in which biopsy was necessary. Dr. Greenough said that they had found, as Dr. Wood had found, that a clean incision was less dangerous than any other method by which one could obtain definite justification for radical operation.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON PEDIATRICS.

Stated Meeting, Held May 13, 1920.

DR. CHARLES HENDEE SMITH IN THE CHAIR.

A Study of the Socially Maladjusted.—Dr. L. PIERCE CLARK presented this subject. (See MEDICAL RECORD, July 3, 1920, xcviii, 1.)

Social Treatment.—Dr. BERNHARD GLUECK discussed this phase of the subject. He said he had not understood that Dr. Clark was going to confine himself to a consideration of a fairly well defined class of the constitutionally inferior. He agreed in the main with Dr. Clark as to the care of these patients and thought there was need in the management of some of them for an institution such as Dr. Clark had outlined. He had been using the George Junior Republic for this purpose. In thinking over the subject he had in mind none of the clearly defined socially maladjusted but rather those less clearly understood and medically not wholly definable individuals concerning whose management one was not justified to speak with such definiteness. The treatment of these individuals was still in the experimental stage and progress rested in the main on a better understanding of those environmental factors which contributed so largely to their social maladjustment. A fuller realization of the tremendous rôle which environmental contacts and influences played in the shaping of character and personality and in determining conduct emphasized the constant necessity in the management of the socially maladjusted of treating other members of the family besides the individuals directly concerned. Even progressive psychiatry leaned altogether too far in the direction of a fixed static concept of the personality, and difficult and hampering traits and characteristics were assumed to be, without much warrant, inborn fixed attributes which predetermined conduct. The case for this assumption was not very strong since we had constant proof of the fluidity and changeability of human characteristics and traits. Social treatment, therefore, embraced as a first step a clear recognition of the importance of the social setting and the social heritage in shaping character and in conditioning conduct. The socially maladjusted, far from being entirely definable on the basis of innate characteristics alone, would continue to constitute the most difficult problem with which psychiatry had to deal until we learned to estimate more accurately social values. Psychiatry in stressing the concept of man as a biological unit had ignored altogether too freely man as a social being. One of the manifestations commonly met with in the socially maladjusted was a feeling of inferiority and a sense of having lost the esteem of one's fellow-beings which rendered adequate social adaptation, if not impossible, certainly very difficult. Medical approach in the strict sense of the term could do very little where the individual must be led by means of social measures such as education, appropriate outlets in his work and play life, cultivation of fellowship, etc., to either a rational acceptance of his inferiority, if such existed, or to an overcoming of it, if that was possible, through the cultivation of such assets as he possessed and through obtaining a gratifying sense of personal worth. Man in his craving for self expression and self realization endeavored to break through the Western Front along some sector of it and it was the object of social treatment to help him discover the sector appropriate to his needs and capacities and to make victory possible. Many of the socially

maladjusted owed their difficulties to a too pronounced discrepancy between personal equipment and aspirations and while this frequently constituted the bridge that made progress possible it frequently meant ruin to the personality if the discrepancy was too wide or the environmental obstacles too serious. Another important task of social treatment was to help man find his proper niche in the scheme of life. A medical approach would continue to be relatively not important in the management of the problems of social maladjustment until it recognized fully the value of the social approach both in the diagnosis and treatment of these cases.

Sex Conflict in Adolescence.—Dr. C. O. CHENEY stated that poor adjustment to society, as shown in bad behavior or misconduct, was the outward manifestation of internal maladjustment or mental conflict. There were no doubt many causes for mental conflict, but one of the most frequent and important causes was the difficulty of adjustment in the sex life. There was a universal and strong inner force demanding the satisfaction of the sex instinct, but there was likewise an almost universal and strong repressing force exerted by society against this satisfaction particularly in children and adolescents. This situation was thus an almost perfect one for the formation of a conflict. Healy in his "Mental Conflicts and Misconduct" had brought out that instances of stealing, truancy, vagrancy, running away from home, mischief making, and cruelty might be the outlets for emotion that had been previously aroused by sexual feelings, or by the acquirement of sexual knowledge. These young people tried to force these feelings and knowledge out of their minds, but as the ideas recurred, to the discomfort of the sufferers, these emotional states resulted in misconduct. This misconduct might be of an impulsive uncontrollable nature and not understood by the individual until analyzed. Finding the trouble, removing the conflict, and aiding in the prevention of its recurrence by change of associates or environment resulted in cessation of the misconduct if the latter had not become a fixed habit. This study of Healy, which could only be briefly mentioned here, was extremely illuminating as to the bearing of sexual conflict, upon delinquency, and was strongly stimulating for further study along the same lines. More familiar to most of us as peculiar manifestations of adolescence were the restlessness, general dissatisfaction with things, irritability, moroseness, shyness, increased religious activity, or interest in socialism, philosophy, or new thought. There was good reason to believe that these were very often merely symptoms of the sex conflict and mental uneasiness, with an attempt at some form of satisfaction and adjustment. There was no means of knowing in how many instances these attempts at adjustment were satisfactory, but those who were continually in contact with maladjusted persons in mental clinics and hospitals did know that there were many adolescents who either had very much difficulty in handling their sex conflicts, or who, never making an adjustment, needed care throughout their lives. They were those types who, finding an outlet only in their own bodies, with the presentation of various physical complaints, made up the psychoneurotics or who, living in sexual phantasy, daydreaming and unreality, showed the symptoms of what was called dementia praecox. The question might have arisen in the minds of his hearers, "Of what concern was all this to the pediatricians"? This could be answered by saying that those in the mental hospitals saw the late or end stages of sexual maladjustment when the habit from conflict had become fixed. In these stages they found from trial that often attempts at helping adjustment were fruitless; they believed the time for help was best afforded in childhood and adolescence and that the pediatrician as the physician of these young people might be of immense help to them. The question might be asked, "What was to be done?" To this certain suggestion might be offered based upon frequent experience with what had not been done. In the first place parents should be disabused of the smug idea that sex was not to be mentioned or thought of until marriage and show them that it was natural for children to have curosity about their own bodies or how they came to be in the world; that evidence of this curiosity should not be met with the proof that it was bad or naughty, but met in a frank straightforward way by explanation. If this policy were carried out there would be less of the antagonism, contempt, or hatred of parents by the grown children when the latter found they had not been played fair with. When children or adolescent patients were brought to the physician with the report that they were nervous or cranky or disobedient, or were otherwise showing that they were not happy in their lives, it would pay to get their confidence, go into their worries and conflicts, advise them and their parents and, if seemed best, change their environment. The older adolescent persons would benefit by some advice about their sexual physiology and be saved from resorting to quacks who would terrify them with horrible tales of the results of self-satisfaction. Attempts to repress and stop an unhealthy sex habit would result only in more conflict if nothing of healthy activity or interest was given the adolescent.

The Inferiority Complex in the Child.—Miss EDITH R. SPAULDING, speaking on this phase of the subject, said that in the reconstruction which was necessary in the lives of the children with whom she had come in contact, the feeling of inferiority from which they suffered seemed to be one of the most important points of attack. She cited two cases in detail which she was seeing at the present time in which this factor was an exceedingly important one. Both of these cases showed many elements and possible points of attack for the process of reeducation. The element to be emphasized in both was the feeling of inferiority, which, in accordance with Adler's theories, appeared to be based on an actual physical or nervous inferiority. It was this weakest point that must be discovered and constructively built up if the child's energies were to be turned into constructive and socialized channels.

Dr. M. A. HARRINGTON said that Dr. Clark had described very adequately the kind of an institution needed to care for this type of person, so he would simply cite a few cases which showed the necessity of individual care in their treatment. The first case described was that of a boy who was incapable of distinguishing between what was his and what belonged to another person. After having committed a number of thefts he was taken to the police station and while there stole the captain's gun. He was sent to the Children's Court and then to Ward's Island, where he came under the speaker's care. He seemed to be a model boy in every other way but simply could not keep his fingers off of what did not belong to him. After he was on the island for a time the people in the office said they would like to have him for a page. They were told of his failing, but were willing to take him for a trial. He was there but a short time when they requested that he be taken away because he was acquiring too many things that did not belong to him. Finally the boy was put in a shoe shop where there was little or nothing to take and in this environment he got along beautifully. He illustrated the type of individual who if left out in the community became a burden to himself and to society, for he was the kind of individual who made the criminal, but under supervision he would get along all right. The second case cited was quite different. In this instance the trouble was not misdirected energy but lack of energy. This boy got along pretty well in school but when he went to work he soon grew tired of it and gave it up. He held several positions with intervals of idleness, and finally gave up work altogether, became discouraged and depressed, and was finally brought to the hospital. There the energy which was lacking in him, was supplied from without, and under steady pressure he got along well. After a time his family thought he could get along outside the institution and he went out, but soon fell back into his old habit of idleness. He was followed up and put into the Y. M. C. A. He was not able to get along outside of an institution. The third case illustrated not misdirected energy, or lack of energy, but poor control. When this boy started in to work he worked hard all day, took work home and worked at night, working eighteen hours a day. He kept it up about three months, then lost heart, gave up his position, and sat about indifferent to everything. He was taken to an institution where

he was treated and put in shape, and when he got out he did the same thing over again. At the hospital he was given work with regular hours, his time was carefully regulated for him, and he was getting along well, but if he went out there would be trouble again. These were three types of individuals who needed institutional supervision.

School Children Who Through Lack of Emotional Control Develop Habits of Truancy.—Miss ELIZABETH FARRELL disagreed with the statement that the maladjusted needed institutional care. She recalled that a few years ago in speaking of the mentally defective and feeble-minded groups, she had stated that there was no one particular adjustment for the normal individual and so there could be no one particular adjustment for the feeble-minded individual, and this same statement held true of the socially maladjustd individual. There could be no blanket system for the management of the socially maladjusted or constitutionally inferior. As there were personal idiosyncrasies so education must be personal and individual. This principle had been applied to physical ills and it was equally applicable in dealing with mental conditions. There was an idea prevalent that this plan of individual prescribing might be applied in private schools but that it could not be done in public schools. This was an erroneous impression; the private schools did no better than the public schools in individual training. Training must be individual, courses of study must not be ironclad, and the effort must be made to adapt the environment to the individual as well as to fit the individual into an environment. Miss Farrell cited cases in which the environment was such that it impinged upon the personality and in which adjustment was made by modifying the environment. There were many ways of caring for the socially maladjusted but it could not be done by any cure-all, be it institutional or extra-institutional. One way was by breaking down inflexible barriers and by doing personal and individual teaching.

Some Medical Aspects of Childhood Delinquency.—Dr. SANGER BROWN said one thing that must have occurred to all while the speakers were discussing adult and child delinquency was whether after all there was not something inherent in the personality either hereditary or constitutionally inherent which made for just these things. He had spent several years with adult personalities such as were described and thought that in children he would find the same traits and qualities, but he must say that he had been unable to find the same traits in children as in adults. In speaking of static personality there was much to be said of the development of the personality in the first ten or fifteen years of life. It developed from the situation in which the child found himself and from the maladjustments and mismanagements to which the child was subjected. All these things went to form character and to make the personality. These things which were minor at first and perhaps open to correction for the first few months, after they had continued for years became traits of character and the emotional reaction became established and formed the adult personality. This pointed the definite indication for treating and modifying such traits in childhood so that many could be saved from adult delinquency. In reviewing the causes of these maladjustments, perhaps one-third were cases of minor neuroses and got into conflict with teachers who did not understand what the trouble was and disciplined the child. The nervous child could not stand discipline and he became a truant, got into bad company and started in the wrong way. If such a child had a special aptitude it should be found and the child given the opportunity to develop it as this might be the means of making a social adjustment. Dr. Glueck said he would like to have more study of the physiological side of these cases. It might be of interest to those present to know that at the Neurological Institute a plan was being outlined for a diagnostic clinic for adolescents where cases showing various maladjustments to life should receive thorough investigation from every possible point of view—physiological, psychological, mental, and physical.

Social Maladjustment as Seen in the Children's Clinic in the Department of Psychopathology at Cornell University.—Dr. L. BLUMGART described the work being done at the Children's Clinic which was started in 1917 in response to need for such a clinic, so that the State Charities Association of New York and the public schools would have a place to bring children for psychiatric advice. The clinic was open one morning a week for just as many hours as the psychiatrist and social worker could spare. The new cases were limited to two a morning in addition to old patients for whom appointments were made. Children were seen from three or four years up to and through adolescence, and in the course of their experience children were met who had committed every antisocial act possible except murder; theft, arson, forgery and bad sex habits were not infrequent. As the work of this clinic became known other institutions sent children for advice. An important aspect of the work was carried on by having a social worker and this side of the work should be emphasized. They had a Smith graduate. One could not carry on this kind of work without a social worker any more than he could practice medicine without a stethoscope or a thermometer. The problems of maladjustment were handled from both angles, the environment or social background and the child itself. The child did not come to the clinic until the complete history was obtained. The history was taken by following an outline taken from Dr. Healy's "The Individual Delinquent" slightly modified to meet the needs of the clinic. In making the mental tests they followed the Terman modification of the Binet-Simon test, and such other tests as Dr. Healy had suggested. These were used to bring out certain qualities or show their absence. The child received a physical and psychiatrical examination and such other examinations as were indicated. The advice of the internist or specialist was available if needed. The child was then interviewed, likewise the parents. The case was then gone over in consultation with a social worker. In this clinic a large variety of conditions were met with. They saw about one hundred patients a year. Dr. Blumgart cited the case of a girl who was maladjusted both at home and at school. In the course of an examination made in the endeavor to ascertain the cause of her trouble, an x-ray examination showed a very small sella turcica. Under pituitrin treatment her home relations were satisfactorily adjusted, and she was able to complete a nine months' business course in three months. When the pituitrin was discontinued she began to relapse. In another case cited separation from the family and supervision served to effect an adjustment. The problem of the psychoneurotic child was far beyond any conception most people had of it. One thing needed was investigation to determine the exact number of maladjusted children. Such an investigation would he believed confirm the findings shown by intelligence tests in the army, that there were a very much larger number of such individuals than we suspected. He hoped it would be done soon. The environmental side must be taken into account as much as the individual side.

Dr. FOSTER KENNEDY took issue with Dr. Clark in regard to the statement that the greatest need of the time was an institution for the care of the consitutional inferior and socially maladjusted. Miss Farrell had taken Dr. Clark to task for that statement and he wished to abet her effort. It was not so much an institution that was needed as some kind of education of the public which would go to prevent the production of these people. It would see that psychiatrists were usually asked in consultation to assume a rôle identical with that which ought to have been assumed by the parent, and often the physician was appealed to on the ground that because of the parent's relationship to the patient his authority was handicapped from the beginning. Dr. Kennedy said he believed that for the most part the physician accepted the paradox of such situation without comment and worse still without thought. Of course when the antisocial trends had developed one was compelled to acquiesce with these demands and occasionally with success. He could not help feeling, however, that as a profession we were not fully cognizant of the root causes of the growing number of the socially maladapted. As civilizations advanced there had been a constantly felt a growing interference with the family instinct by increasing rationalization and growing individualism of the part of the child.

This weakening of parental authority occurred through the loosening of the bonds of religion, the social machinery for the transmission of traditional thought and of course among foreign-speaking people in a new land the parental authority was reduced to a minimum. He said physicians did not read enough history and if they did they were so busy with their individual patients that they did not have time to look thoughtfully at their world and do their share in its education. The immense stability of China and its latent power lay in its ancestor worship, and the Greek and Roman world both degenerated when the *potestas patris* lost the authority of religion and of public opinion. The tremendous strength of the Hebrew race through two thousand years of savage repression had lain mainly in their instinctive partriarchy and reverence for tradition. The loss of these fundamental instincts made for ill discipline in the family and in society had had not a little to do with sapping national strength and with the production of these problems.

Dr. JOHN T. MACCURDY said that as medicine was developing along the lines of prevention and, as all who had spoken had acknowledged that prevention was the most important factor in dealing with the socially maladjusted, he wished to emphasize the fact that the pediatrist met these cases first and had a great opportunity to advise and direct the parents so that defects in adjustment could be corrected early in life. It was a joy to know that a liaison was being established between the pediatrician and the psychiatrist. The pediatrician saw not only the glaring cases of maladjustment, but he saw many of these who were mildly maladjusted, and if he would call upon the psychiatrist, who, while he could not boast great knowledge nevertheless had a limited experience, to examine these cases the course of their psychological development might be modified.

Dr. CLARK, in closing the discussion, agreed with Miss Farrell that there were certain types of mild maladjustment which could be corrected in the ways she had suggested, but it was the more marked types that he had considered in his paper, those in which more profound methods of approach were needed.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

CONNECTICUT STATE MEDICAL EXAMINING BOARD.

November, 1919.

(*Concluded from page* 126)

OBSTETRICS AND GYNECOLOGY.

1. Discuss icterus in the newborn infant.
2. Management of breech presentations.
3. Diagnosis of placenta prævia and management of labor when this condition is present.
4. Discuss uterine inertia and means of accomplishing delivery of child when this occurs.
5. Give full directions for immediate repair in complete laceration of the perineum.
6. Give directions for preparation of patient for elective abdominal hysterectomy.
7. Diagnosis and treatment, operative or otherwise, of malignant disease of the cervix uteri.
8. Treatment of urethral caruncle with especial reference to conservation of function of postoperative urinary control.
9. State what conditions may require curettage and give technique of this operation.
10. A woman of sixty-five who had not menstruated for twenty years has a bloody discharge. Discuss the various conditions that may cause this and differentiate.

SURGERY.

1. Give the differential diagnosis and treatment of cerebral concussion.
2. Give the signs and symptoms of complete division of the musculo-spiral nerve in a gunshot injury.
3. Give the etiology, signs, symptoms, and treatment of acute cholecystitis.
4. Give the etiology, pathology, and treatment of pyonephrosis.
5. Give the diagnosis of early cancer of the breast.
6. Give the etiology and treatment of cervical lymphadenitis.
7. Draw a diagram of a typical Colles' fracture. Give the treatment.
8. Describe the signs, symptoms, and treatment of suppuration in the antrum of Highmore.
9. Give the differential diagnosis of a mass in the scrotum.
10. Describe the symptoms and give the treatment of floating cartilage in the knee-joint.

ANSWERS.

OBSTETRICS AND GYNECOLOGY.

1. *Icterus in the new-born infant. The cause* is not known. It is found most often in premature and weakly infants and in those born in maternity hospitals. The following theories have been held as to its etiology: "(1) *Obstruction to the outflow of bile* by (a) plugs of mucus in the common bile duct; (b) partial blocking of the bile ducts by desquamated epithelium, the result of hyperemia and catarrh of the ducts following on the changes in the circulation which take place at birth; (c) congenital narrowing of the bile ducts; (d) inability of the ducts to carry off the secretion of bile, which is considerable at first; and (e) delayed ligature of the cord. (2) *Pressure on the ducts from without* by (a) the portal and hepatic veins becoming distended in consequence of the changes in the circulation following birth; (b) swelling and edema of Glisson's capsule, the result of engorgement of the umbilical and portal veins—hence the jaundice is hepatogenous. (3) Closure of the umbilical vein, which leads to such a lowering of blood-pressure in the capillaries of the liver that reabsorption of bile takes place. (4) The ductus venosus remains open and thereby allows some portal blood, which contains bile, to pass through it and enter the inferior vena cava." (From *Aids to Diseases of Children.*)

Treatment is, as a rule, unnecessary; a mild laxative or enema may be given; in severe cases treatment is of no use.

2. *Management of breech presentations. "First stage.*—Keep the patient in bed and at rest, so as to preserve the membranes as long as possible. Warn the relatives of the risk to the child. *Second stage.*—Prepare warm towels to wrap around the child's body and limbs, and a warm bath, and everything likely to be required for the treatment of asphyxia. Allow the breach to be born without hurrying it. Support the perineum as in a vertex case. As soon as the body is born as far as the umbilicus, draw down a loop of the cord, at the same time maneuvering it to the corner of the pelvis, where it is least likely to be compressed. This loop by its pulsations is an index of how it is faring with the child. Wrap the limbs and trunk in a warm towel, and hold them slightly toward the mother's abdomen so as to aid the lateral flexion of the body. At the same time exert suprapubic pressure upon the fundus, which aids expulsion and promotes flexion. When the elbows appear the hands may be gently disengaged with the finger. Meantime carefully watch the pulsations of the cord. Provided it is beating regularly and the child is not making convulsive movements, there is no need for anxiety. Wait for the next pain and with the aid of suprapubic pressure expel the head in a fully flexed attitude. *Extraction of the head.*—If the head be delayed more than a few minutes after the birth of the trunk as far as the umbilicus, it will almost certainly require to be artificially aided. The two best methods of doing this are (1) the Prague seizure, and (2) the Mauriceau-Smellie-Veit grip. Both are designed to extract while at the same time promoting flexion. Therefore aid the latter by making the nurse or assistant exert suprapubic pressure while the extraction is being performed. Either method is more easily performed if the mother is in the cross-bed position on her back. This position can only be maintained by the aid of assistants, but if such aid is available it is often desirable to place the mother in this position as soon as the breech reaches the vulva. Anes-

thesia is also required. *Prague seizure.*—Seize the feet and legs by one hand and carry them well forward between the mother's thighs. Place the first and second fingers of the other hand over the child's shoulders to steady the head. Pull upon the legs in a direction at right angles to the mother's abdomen. This forces the occiput against the pubes and so increases flexion, while it also effects extraction, which is controlled by the fingers over the shoulders. In a primipara this method may require such force that the head comes out with a suddenness that causes severe tearing of the perineum. In these cases the second method is perhaps better. *Mauriceau-Smellie-Veit Grip.*—Place the child astride upon the left forearm, and slip the two first fingers of the left hand into the vagina and apply them to the superior maxilla on each side of the nose. With these fingers try to draw down the chin and nose, and so promote flexion. At the same time the two first fingers of the right hand are passed over the shoulders and traction made by them in an upward direction. An alternative is to pass the left forefinger into the mouth, but this is apt to cause injury to the jaw."—(Johnstone's *Midwifery.*)

3. PLACENTA PRÆVIA. *Symptoms.* Sudden hemorrhage, accompanied by syncope, vertigo, restlessness, and feeble pulse. The condition is to be diagnosed from accidental hemorrhage and from rupture of the uterus:

PLACENTA PRÆVIA.	ACCIDENTAL HEMORRHAGE.
Most commonly manifests itself after the sixth month of gestation, but may occur as early as the second month.	Most commonly occurs during the first stage of labor, but may occur at any time during the last three months of pregnancy.
The hemorrhage is abrupt, but painless.	The hemorrhage is sudden, and generally is attended with sharp pain.
There are generally repeated hemorrhages of increasing severity.	Hemorrhage persists until the uterine contents are evacuated or the patient perishes.
There is an edematous condition of the cervix and lower uterine segment, with marked pulsation.	Vaginal examination reveals no deviation from the condition normal to pregnancy.
Cervix is generally quite patulous and within may be detected the placenta.	The cervix is perhaps (if labor be initiated) slightly patulous.
The placental bruit is situated low down.	The placental bruit is in normal position.

(Dorland's *Obstetrics.*)

Ruptured uterus is announced by a sudden, acute, and persistent pain. Sometimes the sound of the rupture is heard by the patient; the symptoms of internal hemorrhage and shock are present—collapse, air-hunger, cyanosis, rapid, feeble pulse; the uterine contractions cease. Vaginal examination shows that the presenting part of the child has receded from its former situation owing to escape of the fetus (partially or completely) through the rent into the abdominal cavity, where it may be felt by abdominal palpation.

Treatment before term: Rest in bed, with or without a *tampon*, will arrest hemorrhage for the time; the sinuses are closed by thrombi, and the case may go on to term or another hemorrhage. The patient should be allowed cold drinks; opium may be used where pain is present. If the hemorrhage is great, it is safer to induce labor at once than to wait. Occasionally no hemorrhage occurs during pregnancy, not even in labor.

Treatment at term: (1) Introduce one or two fingers within the os (the hand being in the vagina) and dissect the placenta from the uterine wall for about three inches from the os uteri in all directions, pushing it to one side if necessary. (2) Rupture the membranes, and if there is an unfavorable presentation, turn the child and make the breech engage in the os; or, if the head presents, the forceps may be used, if speedy delivery is necessary. Stop the hemorrhage by a tampon; this must be tight and thorough. *Accouchement forcé* is indicated; this consists of dilatation of cervix, version and immediate extraction of the child.

4. *Uterine* inertia may be caused by: Debilitated constitution, exhausting disease; uterus weakened because of congenital malformation, inflammation, or too frequent child-bearing; adhesions to neighboring structures; tumors of the uterus or neighboring tissues; distention of the bladder or intestine; displacement of the uterus; premature escape of the liquor amnii; pregnancy in an old primipara; hydramnios; twin pregnancy; fright or mental emotion.

The cervix dilates slowly or not at all; if the membranes are ruptured the fetus makes little or no advance; the woman shows evidences of fatigue and may be anxious or restless; the skin gets dry, the pulse small and rapid, the temperature elevated, the tongue dry and furred, nausea and vomiting may supervene, and delirium and coma may follow. (From Webster's *Obstetrics.*)

Treatment consists in removing the cause if possible; the bladder and bowel should be emptied; opium, morphine and chloral may be given so that the patient may get a little sleep, at the same time food may be administered; the uterus may be massaged through the abdominal walls; hot vaginal douches are sometimes helpful; the vagina may be distended with a rubber bag; if the membranes are ruptured, a Champetier de Ribes bag may be placed in the lower part of the uterus; an anesthetic may be necessary; quinine, strychnine, and ergot have been recommended by some and condemned by others; the newest remedy is pituitrin, which may be injected into the muscles in doses of from 1 to 1½ c.c., provided that the cervix is dilated and that there is no obstruction to delivery.

5. *Lacerated perineum:* "The parts are cleansed and a pledget of sterile cotton or gauze pushed up the vagina to stop any flow from the uterus obscuring the wound. The sutures (preferably of aseptic silk) are passed with a moderately curved needle about two inches long as follows: Beginning at the posterior end of the laceration (that nearer the anus), the needle enters the skin near the edge of the wound and follows a circular course until its point appears at the very bottom of the laceration (a finger of the other hand in the rectum guarding against its penetrating that canal); it then enters the opposite side of the laceration at the bottom of the wound and comes out of the skin opposite its point of entrance, having followed a similar circular course to that pursued on the other side where it first went in. The ends are *loosely* tied or secured by catch-forceps, until the requisite number of sutures are passed in a similar manner (half an inch apart), when the wound is again cleansed, the vaginal plug removed, and the sutures tied tightly enough to coapt the parts without injurious constriction, the order of succession in tying being that in which the sutures were passed.

In "complete" lacerations—those of the third degree—through the sphincter ani to the rectum, the operation is more difficult. The rectal tear is first stitched with *catgut* sutures (a short, curved needle being used) and going through the rectal wall only. The sutures are tied on the inside, so that the knots are on the mucous membrane of the bowel. They begin from above and come down to the sphincter ani, the cut ends of which are drawn out with a tenaculum while the sutures penetrate them. These *catgut* sutures need not be removed; they will digest in the tissues and disappear of themselves. The posterior wall of the vagina is next sutured with fine silk, from above downward toward the hymen. Finally, skin sutures through the perineum itself, including muscles of the pelvic floor (as just described for lacerations of the first and second degrees) complete the operation. The silk sutures may be removed in about a week. Antiseptic dressings are applied as after an ordinary labor, extra care being taken to keep the wound aseptically clean by daily irrigation with the creolin solution."—(King's *Obstetrics.*)

6. *Preparation of patient for abdominal hysterectomy.* "If possible, the patient should take a bath the night before the operation, the body being well scrubbed with soap and warm water. It is well that the vagina should be thoroughly douched with an antiseptic for several days beforehand. Some pack the vagina each night with iodoform gauze as well. A purgative should be given at bed time, and an enema in the

morning. After the bowel is moved, the nurse should thoroughly wash out the lower gut with warm boracic lotion (1 in 30). The evening before the operation a thorough cleansing of the body with soap and warm water should be made. Afterwards the nurse should wash the abdomen, mons veneris, and upper aspect of the thighs with soap, turpentine, and water; the navel should be cleaned with chloroform or ether. It is a good thing to shave the mons veneris at this stage. A poultice of iodic hydrarg. (1 in 4000), or of formalin solution (1 in 1000), is then applied by some to the abdominal wall, and not removed until the patient lies on the operating table. Solutions in glycerin are best. They penetrate the skin, and do not dry up. A purgative is given, and an enema in the morning. The rectum is washed out with warm boric or formalin lotion, and the vagina is douched. The urine is then drawn off if the patient cannot empty her bladder. When the patient is placed on the table, the abdominal dressings are removed; the skin is again washed with turpentine and water, and then bathed with an antiseptic lotion. The abdominal surface is then surrounded with sterilized Mackintosh sheetings, on which sterilized towels, wrung out of a warm antiseptic lotion, are placed."—(Webster's *Diseases of Women.*)

7. *Carcinoma of the cervix:* The symptoms are hemorrhage (which gradually becomes more constant and profuse), pain, and discharge (this is at first serous and odorless, later becoming bloody, mucopurulent, and of a fetid odor). The diagnosis is made on the physical and microscopical examination. The cervix is hard and nodular, and the mucous membrane seems immovably fixed to the underlying tissue. These nodules break down, the entire cervix becomes ulcerated, or large cauliflower-like masses may fill the upper part of the vagina. The diseased tissue is friable and bleeds upon touch. The prognosis is unfavorable unless a radical operation is performed. The treatment consists in removal of the entire uterus, but is contraindicated when the disease has extended to inaccessible organs.

Treatment for inoperable carcinoma of cervix: Careful nursing, scrupulous cleanliness with douches containing potassium permanganate or bichloride of mercury; morphine for the pain; the dead tissue may be removed by scissors or curette; tonics and nourishing food are indicated.

8. *Treatment of urethral caruncle.* There are two methods: —"1. *Excision.*—The patient is anesthetized and secured in the lithotomy position. The urethral orifice is well exposed in a good light and the bladder emptied by means of a catheter. The bill of the speculum is then introduced into the vagina, and the urethra dilated with the uterine dilators up to No. 6. The caruncle is then carefully dissected from the muscular layer of the floor of the urethra, and followed up the canal until its limits are reached, and snipped off. Useful instruments for this purpose are the delicate forceps and scissors employed for operations on the iris. After the caruncle is snipped off there is generally free bleeding; this is easily controlled by passing two thin silk sutures through the cut edge of the urethral mucous membrane and the free margin of the urethral orifice. When the sutures are tied the bleeding ceases. *After treatment.*—Some patients are able to micturate unaided within a few hours after the operation; in others retention lasts for several days, necessitaing the careful use of the catheter thrice each twenty-four hours or oftener. In this event the nurse observes scrupulous cleanliness, always removing the mucus and pus which may have accumulated around the urethral orifice before introducing the catheter. The best method of keeping the catheter clean is to boil it. The patients require to keep their bed for about seven days.

"2. *Destruction by the Cautery.*—This is the simplest method: the patient, duly anesthetized, is arranged as for excision. The vulvar structures are then carefully protected by retractors or the fingers of an assistant, and the caruncle is thoroughly destroyed with the narrow point of the cautery at a red heat. Vaseline is then applied to the cauterized surface. The cautery answers very well for small caruncles. The *after-treatment* is the same as that described after excision." —(Sutton and Giles' *Diseases of Women.*)

9. *Curettage is indicated:* (1) For removal of placental débris, (2) in hemorrhagic endometritis, (3) in some forms of dysmenorrhea (membranous), (4) for diagnostic purposes, (5) in some cases of puerperal sepsis, (6) sometimes to check hemorrhage, due to fibroids. *Contraindications:* (1) The least suspicion of even the possibility of pregnancy; (2) menstruation; (3) acute endometritis; (4) malignant disease of the uterus or vagina; (5) acute pelvic inflammation.

Technique: All antiseptic and aseptic precautions are necessary, the patient should be in the dorsal position, the vagina is to be disinfected, and the cervical canal dilated; a speculum is introduced into the vagina and the cervix is drawn down with volsella; the uterine cavity is irrigated with creolin or lysol; a curette is inserted to the fundus and moved down to the internal os; the operator should begin at one cornu and go in the same direction all around till he reaches the starting point, and if necessary repeat till no more spongy or hyperplastic tissue appears; the fundus should be scraped separately by moving the curette along it from side to side; in going toward the fundus no scraping should be done, and care must be taken not to perforate the uterus; should this happen no fluid must be injected; otherwise the uterus and vagina are again irritated, and one or more strips of iodoform gauze are inserted into the cavity to act either as a hemostatic plug or as a drain, which is diminished with two days' interval and withdrawn on the sixth day. A hemostatic tampon should be placed in the vagina and withdrawn the following day. If any fever arises, the tampon is at once removed and the vagina douched with antiseptic fluid every three hours. If not, the vagina is only swabbed with the same every day, and packed loosely with iodoform gauze. After the final removal of the gauze the antiseptic douche is given twice a day until there is no more discharge. The patient should remain in bed for a week.

10. Hemorrhage is generally the first indication of cancer of the uterus, and every such case should be viewed with suspicion, and a thorough examination should be made. At first this hemorrhage may be slight, but later it increases in amount and is accompanied by other discharges and an offensive odor (in case of carcinoma). The uterus may be freely moveable, moderately enlarged, and the cervix may or may not be normal. On dilating the cervix, a hard irregular ulcerating mass or a soft mass may be found, which on microscopical examination proves to be cancerous. Other possibilities are uterine polypi or fibroids, and endometritis. In the case of uterine fibroids there will be no cachexia (cancer is accompanied by a progressive cachexia), the discharges are less foul, the cervix is not involved, and the microscopic examination is negative as compared with cancer. In endometritis the microscopical examination is different from that in cancer, and the discharge is not offensive and there is no cachexia.

SURGERY.

1. CEREBRAL CONCUSSION. *Symptoms:* In bad cases the patient is unconscious, the respirations faint, the pulse weak, and perhaps slow, the muscles flaccid, the pupils equal and reacting to light, but may in very bad cases be dilated and insensitive to light. The skin is pale and cold, and the sphincters may be relaxed. In a few minutes to a few hours improvement may be ushered in by vomiting, or signs of compression may come on and terminate in death.

In the stage of reaction the pulse, respirations, and mental powers, gradually return to the normal standard. Some headache and irritability may remain for a few days. Permanent defects may be left, such as impairment of vision, hearing, or memory, or neurasthenia.

Treatment: Absolute rest, with the head low, combined with warmth to the surface. Stimulants, such as alcohol and strychnine, should be avoided, except in bad cases, for fear of increasing the hemorrhage. In the stage of reaction the diet should be light and brisk purgatives are necessary. If the unconsciousness is prolonged, the bladder needs to be emptied by a catheter.

Differential diagnosis of concussion and compression of the brain:

	Concussion.	Compression.
Onset	Sudden.	Gradual.
General condition	Can be roused.	Cannot be roused.
Pupils	Equal, react.	Dilated, immobile, perhaps unequal.
Pulse	Slow and weak.	Slow, full, heaving.
Respirations	Slow, shallow, irregular.	Slow, deep, stertorous.
Muscular system.	Relaxed (functional paralysis).	Organic paralysis.
Reflexes	Present.	Absent.
Rectum	Incontinence of feces.	Incontinence of feces.
Bladder	Incontinence of urine.	False incontinence.
Temperature	Subnormal, equal on the two sides.	Subnormal, rising in late stages; may be unequal on the two sides.

—(*Aids to Surgical Diagnosis.*)

2. *Complete division of the musculospiral nerve* causes loss of sensation in the outer side of the forearm and radial half of the back of the hand; wrist drop; and paralysis of the triceps.

3. *Cholecystitis* is generally due to the presence of gall-stones, but it may be caused by typhoid fever, or infection by staphylococci, streptococci, or the colon bacillus. "The *clinical history* varies according to whether the condition is chronic or acute. In the *chronic* variety produced by gall-stones, the symptoms are part of the syndrome characteristic of that condition, and are but little noticeable in themselves. The gall-bladder may be enlarged and a little tender on pressure; should the cystic duct be blocked, it will be distended with mucus or muco-pus according to the degree of irritation present. In the *acute* form it is evidenced by marked pain and tenderness in the right hypochondrium, together with vomiting, constipation, and fever. The constipation may be very marked, as it is due to paralysis of neighboring coils of intestine, and especially the transverse colon. The abdominal wall is held rigid, and the right rectus is very tense; but the enlarged gall-bladder can usually be detected beneath it. As a rule, a sufficiency of adhesions forms to protect the general cavity of the peritoneum, and then the abscess, if unrelieved by art, may burst into the bowel, or may open externally and discharge itself. In the most severe forms sloughing and gangrene of the wall follow (*phlegmonous* or *gangrenous cholecystitis*), and then general peritoneal infection may follow. In the milder forms the inflammation may in time subside, the gall-bladder emptying itself *per vias naturales;* but adhesions of a more or less severe character are likely to be left and may cause much trouble, whilst the gall-bladder itself may shrink and atrophy. *Treatment* consists in dealing with the cause, if such be gall-stones. In the acute variety of suppurative inflammation, the gall-bladder must be opened and drained, or in some cases it may be possible to excise it at once."—(Rose and Carless' *Surgery.*)

4. Pyonephrosis. *Etilogy:* Renal calculus, tuberculous disease, vesical affections, and obstruction in the lower urinary passages.

Pathology: "The infection is commonly an ascending one, being formed by the increased backward pressure. As a result of chronic inflammation, the walls of the ureter become thickened and fused with the peritoneum and surrounding tissues, and the lumen is usually dilated. On section the kidney presents a number of abscess cavities, the intervening parenchyma being pale and tough as a result of chronic interstitial nephritis. Unless there has been antecedent hydronephrosis, the pelvis is usually small in proportion to the greatly enlarged and flask-shaped calyces, which constitute the abscess cavities and form the chief bulk of the kidney. Their communications with the pelvis and with each other are narrowed or obliterated, so that they may be regarded as separate cavities. The purulent contents are often mixed with crumbly masses of phosphates. The mucous membrane of the pelvis and calyces is converted into granulation tissue, and, in advanced cases, becomes the seat of ulceration which eats into the parenchyma. The renal blood-vessels are thickened and narrowed by endarteritis, so that there may be very little hemorrhage when the pedicle is divided. The perinephric cellular tissue is converted into granulation and scar tissue, and is frequently the seat of scattered foci of suppuration, and sometimes a large perinephric abscess is found to communicate directly with one of the dilated calyces. The perinephric suppuration may extend into the psoas and quadratus muscles, or into the cellular planes of the abdominal wall."—(Thomson and Miles' *Manual of Surgery.*)

Treatment: "In the ascending infections the treatment must also concern itself with the disease in the lower urinary organs. So far as the kidney is concerned, the choice lies between nephrotomy and nephrectomy. *Nephrotomy* is indicated in cases in which there is a prospect of re-establishing the outflow through the ureter, and in which all the cavities in the kidney can be opened up and drained without destroying the functions of the organ. *Nephrectomy* is indicated in more severe cases, especially when there is irremediable obstruction in the ureter, and when there is suppuration around the kidney, which can only be properly dealt with after removal of the organ. Nephrectomy is performed by the lumbar route."—(Thomson and Miles' *Manual of Surgery.*)

5. *Beginning carcinoma of the female breast:* "Scirrhous carcinoma is usually met with in women between the ages of thirty-five and fifty, and it often begins while the patient is still menstruating regularly. It sometimes occurs in patients below thirty. The most common site is the upper and outer quadrant of the breast, but it may occur in any part of the gland. Sometimes there is more than one nodule in the breast. In its early stages the condition is quite painless, and the existence of the tumor is usually discovered accidentally. In some cases indrawing of the nipple or dimpling of the skin over the breast first attracts attention. It is often noticed that here is a difference in the level of the two nipples, that of the affected breast being at a higher level than the other (Watson Cheyne). As the disease progresses the patient experiences a dull, aching pain, with occasional sharp twinges shooting through toward the shoulder, up into the neck, or down the inner side of the arm. On palpation, a more or less circumscribed and fairly well-defined tumor of stony hardness may be felt in the substance of the breast. Not being encapsulated, it cannot be moved apart from the breast. When firmly pressed against the chest wall with the flat of the hand the tumor becomes more evident, and its stony hardness is fully appreciated. The skin over the growth may for a long time remain free, but, as the disease progresses, it becomes tacked down, and is later dimpled by contraction of the suspensory ligaments of Cooper. When the skin becomes invaded by the tumor it assumes a characteristically coarse and indurated appearance, aptly compared to that of the skin of an orange or to pig's skin. When the tumor is near the center of the breast, it causes retraction of the nipple by dragging on the large ducts. It cannot be too strongly emphasized that the presence of all or any of these symptoms is not necessary for the diagnosis of cancer, and that when there is any doubt the patient should be given the benefit of an exploratory operation."—(Thomson and Miles' *Manual of Surgery.*)

6. Cervical Lymphadenitis. *Etiology:* Tuberculous or pyogenic infection; it may be found with decayed teeth, tonsillitis, adenoids, middle ear disease, pediculosis, and other affections of the mouth and head. *Treatment:* In acute (non-tuberculous) cases fomentations and incisions are indicated. In chronic, tuberculous cases, hygienic surroundings, nourishing food, removal of all local sources of irritation, and (in absence of lung involvement) the infected glands may be dissected out, or the abscesses opened and curetted.

7. *Colles' fracture* is a transverse fracture at lower end of radius; it is due to falls on the outstretched palm. The line of fracture is about an inch above the wrist, and runs obliquely downwards from behind. The lower fragment is driven backwards and upwards, and

rotated to the radial side, carrying the hand with it into the position of abduction, and leaving the tip of the radius at the same level as, or higher than, the tip of the styloid process of the ulna. The internal lateral ligament of the wrist is ruptured or the styloid process torn off. The fracture is usually impacted, the upper fragment being driven into the lower. The deformity is characteristic, viz.: (1) the hand is abducted; (2) the styloid process is on the same level as, or lower than, the tip of the radius; (3) the upper end of the lower fragment projects above the back of the wrist; on the front is a corresponding depression, while above it the upper fragment projects forward. Union occurs readily, but it is common to get deformity and adhesions about the site of fracture.

Treatment.—"It cannot be too strongly insisted upon that success in the treatment of Colles' fracture with displacement depends chiefly upon complete and accurate reduction, and to enable this to be effected a general anesthetic is of great assistance, especially when impaction exists. The surgeon grasps the patient's hand, as if shaking hands with him, and, resting the palmar surface of the wrist on his bent knee, makes traction through the hand, and counter-extension through the forearm, with lateral movements, if necessary, to undo impaction. When the fragments are freed from one another, the wrist is flexed, and the hand carried to the ulnar side, while the fragments are moulded into position. When reduction is complete, the deformity almost entirely disappears, and the two styloid processes regain their normal positions relative to one another. As there is no tendency to redisplacement, no retentive apparatus is required, but, as it adds to the patient's comfort and sense of security, a firm flannel bandage, a broad strip of adhesive plaster, or a poroplastic wristlet may be applied. In severe cases, however, anterior and posterior splints, similar to those used for fracture of both bones of the forearm, or a dorsal splint padded so as to flex the wrist to an angle of 45°, but somewhat narrower, may be employed. The hand and forearm are in any case supported in a sling. To avoid the stiffness which often follows this fracture, the massage and gentle movement of the wrist and fingers should be carried out from the first, the range of movement being gradually increased until the function of the joints is perfectly restored. If splints are used, they should be discarded in a week, and the patient is then encouraged to use the wrist freely."—(Thomson and Miles' *Manual of Surgery.*)

8. SUPPURATION IN THE ANTRUM OF HIGHMORE. *Symptoms:* "There is pain, tenderness on pressing over the canine fossa or on tapping the teeth of the upper jaw, and sometimes swelling of the cheek. The complaint of a bad odor or taste, the reappearance of pus in the middle meatus after mopping it away and directing the patient to bend his head well forward, and opacity on trans-illumination of the suspected cavity are signs which strongly suggest an affection of the maxillary sinus. The withdrawal of pus by a puncture through the thin outer wall of the inferior meatus of the nose with a fine trocar and cannula will establish the diagnosis. The *treatment* consists in opening and draining the antrum. If the infection is due to a carious tooth this should be extracted, the socket opened up and drainage established through it. If the teeth are sound the antrum is opened through the canine fossa and its walls curetted, after which the cavity is packed with iodoform worsted. To avoid the risk of reinfecting the cavity from the mouth, an opening may be made into the nose, by removing the anterior portion of the nasal wall of the antrum and part of the inferior turbinated bone, after which the incision in the buccal mucous membrane is closed with sutures."—(Thomson and Miles' *Surgery.*)

9. DIFFERENTIAL DIAGNOSIS OF A MASS IN THE SCROTUM. *Hernia* may be known by the impulse at the neck, its ready reducibility (usually) on the patient's lying down, with slip or gurgle, the facility with which now the external ring and cord can be felt, its speedy descent when the patient stands up and coughs, and its lack of translucency. The thickened tissue felt in the scrotum after the return of the hernia is merely the sac, and not to be taken for anything more abnormal. If the hernia is irreducible, there will still be impulse, the feeling of coils of bowel or of granular omentum; and the irreducibility will be either temporary—due to neglect of the bowels or disordered digestion—or permanent, owing to repeated "bowel attacks," accompanied by slight colicky pains.

Hydrocele, known by the absence of impulse, by its pyriform shape, fluctuation, and almost unvarying translucency. The testis is at the back, as shown by its sensitiveness and opacity. The increase has been slow, painless, and usually occurs in patients of middle or later life, though it is not uncommon in younger men after strain, injury, or in association with acute epididymitis.

Hematocele will be known, when at all recent, by its rapid onset after a blow or the tapping of a hydrocele; its condition, at first fluid, then more solid; its weight and want of translucency, and the position of the testicle at the back.

Epididymitis is nearly always due to some urethral irritation, most frequently gonorrhea. It shows itself as a rapidly forming swelling, acute and tender, at the outer and back part of the testis, from which at first it is situated by a distinct furrow. Nausea, chilliness, and pyrexia accompany it.

Varicocele will be known by the soft, worm-like bluish coils of enlarged veins around and along the cord, the relaxed scrotum, and the dropped testicle. It sometimes gives an impulse on coughing, and is not completely reducible.—(From Heath's *Dictionary of Practical Surgery.*)

10. FLOATING CARTILAGE OF THE KNEE JOINT.—*Symptoms:* "Violent pain in the knee joint, chiefly on the inner side over the lateral ligament. The knee is locked in a semi-flexed position. Synovial effusion with its usual signs appears within a few hours. Later, and in the absence of proper treatment, recurrent attacks of synovitis often occur in any action of flexion and rotation of the knee. Tenderness is most marked on pressure over the tibial attachment of the internal lateral ligament. Very rarely a lump or gap can be felt in the position of the cartilage."

Treatment: "Reduction by flexion and extension of the joint. Immobilization on a back-splint for six weeks, followed by firm bandaging for three months. This treatment should be adopted in all recent cases occurring for the first time. Operation (for all recurrent cases): If thorough immobilization has been neglected at first, it is useless later. Incision in a transverse direction over the edge of the affected cartilage. Open the joint. Remove completely all injured or displaced parts of the cartilage. Cut any tags of hypertrophied synovial membrane. Close without drainage. Retentive apparatus (when operation is refused or undesirable in chronic cases): The mechanism embraces the joint and while allowing flexion does not permit of any rotation."—(Grove's *Synopsis of Surgery.*)

DIAGNOSIS AND TREATMENT OF RECURRENT CHOLECYSTITIS WITHOUT STONES.*

BY MAX EINHORN, M.D.,
VISITING PHYSICIAN TO THE LENOX HILL HOSPITAL,
AND
WILLY MEYER, M.D.,
NEW YORK
ATTENDING SURGEON TO THE LENOX HILL HOSPITAL,
(From the Lenox Hill Hospital, New York.)

THE last two or three years have given us frequent opportunity to deal with gall-bladder inflammations without stones in which the diagnosis as well as the treatment presented a rather difficult problem. Although some surgeons notably, the Mayos, Dr. R. S. Fowler[1] of Brooklyn and John B. Deaver[2] of Philadelphia, excise the gallbladder when chronically inflamed, the majority of clinicians and not a few surgeons doubt the advisability of extirpating a gallbladder—even if diseased—so long as it does not contain stones. Inasmuch as our opinion is contrary to this commonly held view, we thought it best to present our experience regarding this subject before you.

As the basis of this paper we select eighteen cases of recurrent cholecystitis without stones that have been operated upon, and in this way the diagnosis corroborated *per autopsiam in vivo*. A few of these cases we shall describe in detail while all will be mentioned in the table stating the findings of the duodenal contents.

CASE I.—Albert De V., 25 years, October 22, 1919. In January, 1919, patient was seized with a severe sharp, knife-like pain, lasting several hours. The attacks occurred at intervals of about once every month up until July, 1919. Since that time they came on every week to 10 days. The pain had no relation to food, radiated to the left side and was relieved only by hypodermics of morphine. There was no vomiting, no belching of gas, bowels were normal. During the attacks the patient would lose 2 or 3 pounds, but he would regain this weight in the intervals of euphoria. He was jaundiced once shortly after an attack. Patient has always been well prior to the present illness.

Examination of the abdomen revealed a slightly enlarged liver. There was an area below the right costal margin painful to pressure. The gastric contents showed: HCl +; acidity =65; the string test revealed a blood stain at 18 inches distance from the lips. The duodednal contents aspirated in the fasting condition were turbid, grayish green looking. A diagnosis of gastric ulcer and cholecystitis was made. Patient was treated by duodenal alimentation and was then operated upon by Dr. Willy Meyer for his gallbladder condition. Wassermann was negative.

November 21, examination per rectum: appendix tightly adherent to meso-appendix, old bands. Typical removal; contains large fecal concretion with proximal stricture. No stones in gall bladder which is blue, glistering, soft; contents turbid; cholecystectomy performed; which was difficult on account of firm adhesions in liver bed; same at duct; juncture of both covered by large adherent glands. Drainage and closure as usual. Culture from aspirated bile of gallbladder showed colon bacilli.

November 24, patient doing nicely.

March, 1920.—Patient feels perfectly well; has had no attacks since the operation.

CASE II.—Mrs. Rose S., 38 years. February 4, 1920. The patient gave a history of abdominal cramps on and off for 18 months. Five weeks ago had severe abdominal cramps in right epigastric region radiating to right shoulder associated with some jaundice and light colored stools; two weeks later another attack came on, and since then has had them daily. No vomiting. The appendix was removed two years ago. Upon examination a mass is palpable in the region of the gallbladder, which has an oval configuration of about 1½ to 2 inches in length and one inch in width and feels elastic and somewhat pliable. This appears to be the gallbladder. Temperature upon admission until operation, normal to 100°.

Duodenal contents: Greenish yellow; turbid; alk = 20; A = +; S = +; T = +; microscopically, bilirubin calcium and cholesterin crystals; bacteria.

Blood count=R. B. C., 4,600,000; W. B. C., 8,800; polys, 80 per cent.; lym,. 20 per cent.; Hb., 80 per cent. Wassermann negative; String test negative; *x*-ray negative.

Gastric contents: HCl, 0; Acidity, present; Blood +.

On March 8, 1920, cholecystectomy was performed by Dr. Willy Meyer. The bile aspirated from the gallbladder at operation was dark brown and turbid.

CASE III.—Mrs. Eva B., 43 years old. March 20, 1919. She has had attacks of pain in the epigastric region on and off for five years. Pains radiate across abdomen and are accompanied by vomiting. Sometimes they come on after meals and at other times they have no relation to the food. Two months ago the patient ate some chopped meat and an attack came on. This brought her to the hospital. Jaundice was present two years ago.

Temperature normal up until the time of the operation. Duodenal contents: yellowish brown, turbid; alk = 25; A, 6; S, 3; T = 5. Gastric contents: HCl = 20; Acidity = 40; Blood, +.

Cholecystectomy and appendectomy performed by Dr. Willy Meyer on April 1, 1919. The gallbladder was glistening, not blue; the bile aspirated from the gallbladder at operation was greenish and very turbid. Anatomical diagnosis: Chronic catarrhal cholecystitis; chronic appendicitis.

At the operation the following was found: Pyloric ring irregular, slightly infiltrated; pannus, with adhesions upward, but not to liver; probably additional duodenal ulcer, but clinically symptoms missing.

Later on at home, she had vomiting spells and was then readmitted to the hospital. No food retention was found in the stomach. She recovered.

CASE IV.—John A. H., aged 29 years, admitted May 5, 1919. Four weeks ago patient became dizzy; felt like fainting; two weeks later had pain across the abdomen, but it did not radiate and had no relation to food. The bowels were constipated since onset; no vomiting.

*Read before the American Gastroenterological Assoc., at Atlantic City, N. J., on May 3, 1920.

Physical signs: Tenderness in right upper quadrant. The edge of a tumor mass can be made out in right upper quadrant. The temperature on admission was 103°, then varied from 102° to 105° until the operation after which it fell to normal in 10 days.

Duodenal contents: yellow, very turbid; alk = 25; A = 6; S = 1; T = 1; many bacteria, pus cells, and cholesterin and calcium bilirubin crystals. Blood count: W. B. C. = 20, 400; polys. = 86 per cent.; lym., 14 per cent.

Cholesterol = 120; bile sterile; Widal negative; complement fixation for tuberculosis negative; Wassermann—0; gastric contents, HCl. = 50; acidity = 75; feces negative.

Anatomical diagnosis: Chronic periappendicitis; catarrhal cholecystitis.

On June 5, 1919, a cholecystectomy and appendectomy were performed by Dr. Rehling.

CASE V.—Max S., age 50 years, admitted February 17, 1920. Five weeks ago the patient had a gnawing pain in midline region of the stomach, 4 hours after the noonday meal; the pain was relieved by the taking of food; no vomiting, patient belched gas after meals, lost 15 pounds in two months. Wassermann was positive two years ago; had ten salvarsan injections. The bowels were regular.

Physical signs: Liver palpable two fingers below the epigastric angle. Heart sounds of poor quality; short systolic murmur apical; pupils sluggish to light.

Duodenal contents: yellow pea-soup appearance; turbid; alk = 20; A = +; S = 2; T = 6; cholesterin crystals; bacteria and mucus. Gastric contents: HCl. = 14; acidity = 26; no blood; string-test negative; feces negative. Wassermann negative at present. Blood count: W. B. C., 5,720; polys., 58 per cent; lym., 42 per cent.; Hb., 80 per cent. Temperature, slight elevation up to 100. The *x*-ray apparently showed penetrating gastric ulcer; persistent defect in the lesser curvature.

Cholecystectomy was performed by Dr. Willy Meyer on February 23. No ulcer was found. Bile from the gallbladder, alk. = 120; dark green like Kulmbacher beer.

CASE VI.—Jacob R., age 40 years. Admitted September 30, 1919, with a history of having suffered with pain in the right upper quadrant for four years, the attacks coming on gradually and leaving gradually, the pain radiating to both shoulders; no jaundice; lost 30 pounds in 3 or 4 months..

Physical examination shows slight rigidity and extreme tenderness over the entire right side; the liver is enlarged and very tender at the site of the gallbladder. *X*-ray negative; Wassermann, 0; blood count, W. B. C. = 7,550; polys. = 62 per cent; lym. = 38 per cent.; R. B. C., 6,000,000. Temperature, 102°.

Duodenal contents yellow with a tinge of green, turbid; alk = 30; A = 8; S = 1; T = 1; microscopically are seen cholesterin crystals, bacteria, and white blood cells. Gastric contents: HCl = 66; acidity = 82; blood, negative. String test negative.

Cholecystectomy and appendectomy performed by Dr. Torek on November 1, 1919. The contents of the excised gallbladder = culture sterile. Pathological diagnosis, catarrhal appendicitis; slight localized inflammation of the gallbladder. The temperature dropped to normal two days after the operation.

CASE VII.—Mrs. D. Sick for many years. Frequent pain in the epigastric region and had to be most careful in diet; gained twenty pounds lately under proper management; this speaks much against carcinoma though the presence of acanthosis nigricans suggests the same. At the first office call tenderness was found in the region of the gallbladder; duodenal contents found turbid with cholesterin crystals.

February 17, 1919. A Perthes incision was made and lengthened to the xiphoid; stomach large and ptosed; no sign of ulcer at pylorus or duodenum nor of carcinoma in entire length of stomach, duodenum, or head of the pancreas, large intestine or liver; gallbladder large, not blue glistening, evidently chronically inflamed; appendectomy was performed with difficulty. "In view of duodenal findings" cholecystectomy was performed (ligature at the cystic duct left for the further examination); usual drainage; aspiration of the gallbladder shows pronouncedly turbid bile. Bacteriological examination of the aspirated bile from the excised gallbladder showed it to be sterile.

March 1. Tampon and rubber removed.

In conjunction with the above cases we give in the following table a detailed description of the duodenal contents as found in all the patients before the operation, and in some also of the bile aspirated from the gallbladder during the operation.

In looking over the cases with regard to their symptomatology two types can be easily discerned. Type I is characterized by distinct attacks of colicky pains in the upper abdomen (usually on the right side or exceptionally on the left side), lasting from one to several days, followed by perfect relief of symptoms. One or more such attacks will have occurred before the patient consults his physician. During the attack there is often a slight rise in temperature accompanied by a moderate leucocytosis and an increase of the polymorphonuclear white blood cells.

Type II shows no distinct attacks. The patient usually complains of slight distress either in the midepigastrium, especially after meals, or somewhat to the right of the linea alba covering, principally the right hypochrondriac region. While there is usually no rise in temperature, at times the latter may occur in a pronounced manner. The patient is then debilitated and bedridden.

In both types the objective findings are as follows:

The liver is frequently found somewhat enlarged. Palpation to the right of the linea alba in the area situated between the costal margin and the navel line occasionally elicits pain, especially during an inspiration. In the same region there is at times found the *défense musculaire* of the rectus abdominis muscle.

The bile, as found by aspiration of the duodenal contents in the fasting condition of the patient, is usually turbid, presenting a yellow-brownish appearance. Occasionally it looks greenish. Microscopically numerous bacteria and cocci are frequently found; often pus cells; cholesterin- and bilirubin-calcium crystals are likewise encountered, but in comparatively small numbers. The alkalinity and the pancreatic ferments do not, as a rule, deviate much from the normal.

In the above-mentioned eighteen cases of true cholecystitis verified by operation and pathological examination, the duodenal contents were pretty clear in one (Mr. B., No. 11), while the rest showed pronounced turbidity with all the attributes mentioned in the previous paragraph.

In quite a number of these patients the appendix was found to be considerably diseased. In every one of the patients (excepting a few who had undergone appendectomy before) the appendix was removed as a prophylactic measure. A few of the cases were complicated with peptic ulcers, requiring special treatment for the latter affection.

At the operation the gallbladder, as stated above, was thoroughly examined by inspection, palpation, and aspiration. In all the cases mentioned it was found diseased—either thickened or glistening whitish, or the bile was dark black and turbid or containing much mucus and slightly thickened material. The pathological anatomical diagnosis, as

TABLE OF EXAMINATION OF THE DUODENAL CONTENTS (BILE) IN 18 CASES OF CHRONIC CHOLECYSTITIS WITHOUT STONES OPERATED UPON.

Name.	Date.	Alkalinity	Amylopsin	Steapsin	Trypsin	Appearance and Microscopical Findings.	Remarks.
Mrs. M.	4-15-18	20	10	3	1	Yellow; slightly turbid.	Cholecystectomy by Dr. Willy Meyer.
Mrs. B.	3-30-19	25	6	3	5	Yellowish brown; turbid.	Appendectomy and Cholecystectomy by Dr. Willy Meyer; gall-bladder at operation glistening; not blue; bile-greenish and turbid. Pathological diagnosis-chronic catarrhal cholecystitis; chronic appendicitis.
Mrs. D.	2-14-19	30	6	2	4	Very turbid; yellow; green, pea-soup appearance; cholesterin and calcium oxalate crystals.	Cholecystectomy by Dr. Willy Meyer.
Mr. A. de V.	11-2-19	25	11	2	5	Reddish yellow; turbid, pus cells; cholesterin crystals.	Cholecystectomy by Dr. Willy Meyer; Bile from gallbladder turbid; culture showed colon bacilli; gallbladder at operation-glistening, blue, and soft.
Mr. K.	11-2-19	25	7	2	2	Yellowish green; turbid; pus corpuscles.	Cholecystectomy; Dr. Willy Meyer; Bile from gallbladder, greenish and turbid; at operation right lobe of liver infiltrated.
Mrs. G.	11-25-19	30	10	1	3	Yellowish green; turbid.	Cholecystectomy by Dr. Willy Meyer; Bile from gallbladder, dark green; turbid; Pathological diagnosis-subacute catarrhal cholecystitis.
Miss P.	2-6-20	20	10	1	2	Yellow turbid; small cholesterin crystals; calcium bilirubin crystals; pus cells.	Cholecystectomy by Dr. Willy Meyer. Bile from gallbladder, green and turbid.
Mr. R.	10-15-19	30	8	1	1	Yellow; tinge of green; turbid; pus cells; cholesterin crystals; bacteria.	Cholecystectomy and appendectomy, by Dr. Torek. Pathological diagnosis, catarrhal appendicitis; slight localized inflammation of gallbladder.
Mr. H.	5-28-19	25	6	1	1	Yellow, very turbid; cholesterin crystals; bacteria; calcium bilirubin crystals; pus cells.	Cholecystectomy and appendectomy by Dr. Willy Meyer; Pathological diagnosis, chronic periappendicitis; chronic cholecystitis.
Rev. H.	1-25-19	15	5	Trace	0	Light yellow; turbid; few cholesterin and tyrosin crystals; mucus; pus cells.	Cholecystectomy by Dr. Willy Meyer; Pathological diagnosis, chronic cholecystitis.
Mr. B.	2-16-20	20	10	Trace	1	Golden yellow; clear.	Bile from gallbladder at operation dark colored. Cholecystectomy by Dr. Willy Meyer. Pathological diagnosis, catarrhal cholecystitis.
Mr. S.	2-16-20	30	..	2	6	Yellow; pea-soup appearance; turbid; mucus; cholesterin crystals; bacteria; pus cells.	Cholecystectomy by Dr. Willy Meyer; Bile from gallbladder dark green like Kulmbacher beer.
Mr. P.	2-20-20	20	..	.	.	Greyish, reddish tinge; turbid.	Appendectomy and Cholecystectomy by Dr. Willy Meyer; Bile from gallbladder dark and black at operation, gallbladder shows enlarged vessels; bluish and glistening.
Mr. B.	3-21-20	20	6	1	5	Greyish; turbid; tinge of yellow; many cholesterin and calcium bilirubin crystals; mucus; ova.	Cholecystectomy by Dr. Willy Meyer.
Mr. D.	3-24-20	20	6	1	3	Greenish yellow fluid; mucus.	Cholecystectomy by Dr. Willy Meyer; Bile from gallbladder dark, green; turbid alk, 60.
Mr. F.	3-16-20	20	4	1	2	Yellow; turbid; cholesterin crystals; mucus; epithelial cells.	Cholecystectomy by Dr. Willy Meyer; Bile from gallbladder turbid; dark green.
Mrs. S.	3-1 -20	20	..	.	.	Greenish yellow; turbid; small cholesterin crystals; calcium bilirubin crystals; bacteria; mucus; epithelial cells.	Cholecystectomy by Dr. Willy Meyer; Bile from gallbladder dark brown, turbid.
Mr. B.	4-20-20	35	8	1	3	Greenish yellow; turbid; cholesterin crystals; epithelial cells; mucus; pus cells.	Cholecystectomy by Dr. Willy Meyer.

given by the pathologist of the hospital, is stated in each case examined. The gallbladder was always found diseased and the diagnosis of cholecystitis corroborated.

Diagnosis.—The recognition of chronic cholecystitis without stones is not difficult. In making a diagnosis, however, in most instances, merely the cholecystitis can be made out, while the absence of stones cannot be foretold until after the operation. According to Smithies' even in distinct cases of biliary colic, stones are found in 57 per cent., while in 43 per cent. no calculi are present. In exceptional cases the probable occurrence of a cholecystitis without stones can be predicted.

The diagnosis of cholecystitis is based upon the symptoms (colicky pains in the upper abdomen; distress in the epigastrium radiating backward to the right) in conjunction with the presence of pronounced turbid bile in the duodenum in the fasting condition of the patient, as found by means of the duodenal tube. The existence of a considerable leucocytosis, with an increase of the polynuclear elements, enhances the diagnosis and indicates the severity of the lesion.

Treatment.—Mild cases of cholecystitis yield often to medical treatment. The same consists in ample rest, frequent small meals, plenty of water, saline aperients (Carlsbad, Saratoga, French Lick Springs) washing of the duodenum with a weak argyrol or ichthyol solution (1 to 2 per cent).

Frequently recurring attacks of cholecystitis, especially when accompanied by even a slight rise of temperature, require operative intervention. The same applies to forms of cholecystitis throwing the patient into a state of invalidism or endangering life by infection. The operation consists in removing the offending organ (cholecystectomy).

The Reasons for and the Results of the Operation.—The reasons for the operation in the cases described were: (1) Recurrent troubles not yielding to the usual modes of treatment. (2) Febrile conditions bearing the stamp of infection and apparently due to the gallbladder, endangering life.

The results were uniformly good, excepting in one case in which recurring attacks of jaundice and cholangitis persisted after the operation.

Conclusions.—1. A diagnosis of chronic recurrent cholecystitis can frequently be made, even when stones are absent, by the symptoms present in conjunction with a direct examination of the bile.

2. When operating for cholecystitis a chronically diseased gallbladder should be excised, even if no stones are found in the affected organ. M. E.

ADDITIONAL REMARKS FROM THE SURGEON'S POINT OF VIEW.

In patients complaining of distress in the upper abdomen physicians and surgeons will think of a diseased stomach, duodenum, gallbladder, or pancreas; the appendix and kidney also come into consideration.

After we have obtained a most careful history of the case and made an equally thorough clinical examination, trying to make a preliminary diagnosis, the laboratory nowadays steps in for differentiation. Examination of stomach contents, string test, *x*-rays, Wassermann reaction, and stool analysis pave the way for the correct diagnosis of gastric or duodenal affections.

For the determination of gallbladder disease there are at our disposal to-day, citing them in accordance with the time of their introduction: radiography, cholesterol test of the blood, and examination of the duodenal contents.

The *x*-rays, according to some writers, show stones in about 15 to 20 per cent. of the cases; others have found positive results in somewhat over 30 per cent., while others still claim much higher figures. The rays cannot assist in shedding light on the condition of patients who suffer from an inflamed gallbladder without stones, though they can show adhesions (insufflation of oxygen into the peritoneal cavity).*

The cholesterol test is generally believed to be unreliable.

The examination of the duodenal contents with the help of the Einhorn tube, chemically, microscopically, and bacteriologically, bids fair to throw a great deal of additional light on the subject. At the present moment, it appears to be the best and most reliable means we possess for diagnosing an affection of gallbladder or bile ducts.

For several years Dr. Einhorn and myself have systematically added the examination of the duodenal contents to the other laboratory tests, and then compared the condition of the bile as it is physiologically discharged into the duodenum previous to surgical interference, with later operative findings.

We can state that the pre-, inter-, and post-operative examinations tallied in almost every instance. It is, of course, necessary to leave the duodenal tube in place for a number of hours (3 or 4) and then aspirate every half hour. In some cases, *e.g.* if the cystic duct is strictured or a stone completely obstructs it, the secretion will represent fresh liver bile only. If the examination before operation had shown the bile discharged through Vater's papilla, blackish green or brown in color, and turbid, with cholesterin or bilirubin crystals and pus corpuscles, aspiration of the bile with a needle introduced into the gallbladder during the operation usually showed the same thing.

Inasmuch as the culture of the bile aspirated during operation not infrequently failed to show bacterial growth, the question arose: is a blackish-green or dark brown bile pathological. We believe it is. Physiologists teach that normal bile from the hepathic duct as well as from the gallbladder is golden yellow in color. In animals possessing a gallbladder, the bile within the latter has uniformly shown a golden-brown color. Furthermore, as stated by Dr. G. L. Rohdenberg, pathologist of the Lenox Hill Hospital, "Two healthy young men in the twenties of life, who were autopsied within 5 minutes after death, the latter having followed legal electrocution, showed a golden-yellow bile in the gallbladder." He adds, "The fact that death by this method raises the body temperature to 120°-150° F. may, of course, have had some effect on the fluid content of the gallbladder." Again he states: "That some of the fluid from diseased gallbladders is sterile, is not surprising; first, because bile is lytic for several types of bacteria; second, because it is probable that the bacteria do their damage in the tissues of the gallbladder wall."

Personally I would add that possibly the frequent negative results of culturing bacteria in the dark green or brown turbid bile, as aspirated from the gallbladder during operation, may depend upon the procedure itself. In order to give results the culture has to be made on an anaerobic plan, because naturally there is no air within the gallbladder. It, furthermore, is possible that, with the ever-shifting fluid within the bladder itself, the bacteria may be found only here and there, and also may vary, and just that particular bit of bile that is used for making the culture may not contain any. In order to obtain more reliable results, we have therefore adopted the following plan:

We always have a competent assistant of the pathological laboratory at the operating table. Immediately after aspiration, he receives the syringe with the bile from the gallbladder and spreads it on the

*This at least had been the generally accepted opinion of clinicians up to date. The recent presentation of the subject before the American Gastroenterological Association, May 3, 1920, by Dr. A. W. George of Boston makes us entertain the hope that radiography is going to show disease of the gallbladder in almost 90 per cent. of the cases. The rays frequently demonstrate a distinct contour line of the gallbladder without stones. At the present moment it is believed that if they do so the gallbladder is pathological. A healthy gall bladder does not show on the plate under ordinary conditions. The pneumoperitoneum (oxygen insufflation), however, does do so.

agar plates. After the cholecystectomy, the viscus is bisected transversely; the cystic duct with the proximal half of the gallbladder is placed in a 5 per cent. formalin solution, so as to preserve the mucosa which otherwise for pathological examination rapidly undergoes autolysis, while the fundus with the distal half is used for tissue culture. Examination has repeatedly proved the presence of bacteria in the gallbladder wall, though the turbid, greenish black bile from the bladder failed to show a growth. Proceeding systematically in this way, we hope gradually to gain data of value in post-operative laboratory examination—data which will allow of definite diagnostic conclusions on basis of preoperative findings.

So far we have found that recurrent cholecystitis without stones is a much more frequent disease than is generally believed, that it seems to occur oftener in the male than in the female sex, that many patients with vague complaints of distress of the normal equilibrium in the upper abdomen, suspected to be referable to a gastric or duodenal ulcer, suffer from cholecystitis, often without stones.

Persistently recurring pains in the left side of the upper abdomen as well as in the region of the heart—so frequently diagnosed in the male as spurious angina—are also frequently due to a gallbladder infection. I have seen a number of such instances. (Proceedings of N. Y. Surg. Soc., 1919, *Annals of Surg.*) Complete gastric analysis and radiography of stomach and of the left kidney for stone has given a negative result, the urine, too, having been found normal. But examination of the duodenal contents gave the right clue, and was corroborated by operative findings. These pains on the left side of the abdomen are more often associated with cholecystitis and cholelithiasis than with cholecystitis without stones.

Of course, not too much must be demanded from this mode of examination. It cannot throw definite light on the question whether the turbid bile is discharged from the gallbladder, or from the liver and bile ducts—at least not thus far.

Perhaps the further working out of the problem will permit us to do this also. I would but refer to Meltzer's proposition to instill a solution of magnesium sulphate into the duodenum in order to stimulate the discharge of bile.

However, the method will, I believe, be of importance in clearing up the cases of recurrent colicky pain after cholecystectomy. These pains do not necessarily always depend on the gradual descent of calculi, or of "liver gravel" found within the branches of the hepatic ducts or a spasm of the constrictor muscle at the papilla of Vater, which the duodenal tube may greatly assist in proving.

With reference to the surgery of the gallbladder, but a few words:

1. So far as indications point to-day, it appears to be better surgery to extirpate the infected gallbladder without stones, than to drain, or leave it in place. Such a bladder, stitched to the abdominal wall, though at first drained for quite some time, may in the future come to represent an infected focus from which the system is intermittently flooded with toxins. If secondary cholecystectomy is refused by the patient, chronic pancreatitis may develop in addition to the chronic recurring cholecystitis, and invalidism may develop for the remainder of life.

It is also most likely that the chronic cholecystitis *without stones* which often shows bacteria suspended in its bile and habitating within its walls, is to be considered "the precursor" of chronic cholecystitis *with stones* in many instances.

2. I prefer operating from the fundus toward the cystic duct, in spite of the somewhat increased hemorrhage from the gallbladder bed. In this way one will always be ready properly to meet any of the anomalies so often present near the junction of the cystic and the common ducts, so beautifully demonstrated by Eisendraht's specimens. One will also be able always to ligate the cystic duct very close to the common—an important point, inasmuch as by so doing nature's effort to distend the stump and form a miniature new gallbladder with all the inherent faults of the original larger one will be forestalled.

3. The results of cholecystectomy are almost as good as those of appendectomy. Of 100 patients operated on we see practically 100 get well. Something extraordinary, something unforeseen, beyond the control of the attending surgeon has to happen to have the operative result disappoint expectations.

4. To close the abdomen completely, without drainage, as in appendectomy, seems inadvisable; a leak may occur permitting infected liver bile to pass into the peritoneal cavity, at the tied stump of the cystic duct, and thus cause death from septic peritonitis after an original straight recovery. Drainage is more cumbersome, but meets all emergencies. The patient's safety is the first law.

5. The principal advantage accruing from the preliminary more refined diagnosis by means of the examination of the duodenal contents, for the patient as well as for the surgeon, is the indication derived from it with reference to the place of the incision. Every surgeon, I am sure, has often felt dissatisfaction on cutting down on the appendix and then introducing the hand into the abdomen and palpating the gallbladder region. When using the intermuscular (McBurney's) incision, the hand cannot be introduced, and the para- or per-rectus cut must be made long enough to permit the hand to pass. Having the fingers in place, we can but determine the presence or absence of calculi in the gallbladder; we cannot clearly feel pericystic adhesions, omental attachments, etc. When we know, however, before we proceed with the operation, that the bile is turbid, it becomes our duty to cut down on the gallbladder and then pull up the cecum with the lower portion of the ileum into this wound, and remove the appendix. Then we are able to view the gallbladder and its immediate surroundings; we can inspect stomach, duodenum, and liver, can palpate the head of the pancreas, common and hepatic ducts—in other words, can make the usual survey of the upper abdomen, the same as we are wont to do in other gallbladder operations. Finally we can aspirate the gallbladder and find out the quality of its contents, comparing it with that of the bile examined before operation, and on the basis of this finding determine the necessary operative procedure.

It is interesting to note how the whole method of examination before the operative procedure, as de-

scribed above, has changed the indication formerly derived from the results of inspecting and palpating the gallbladder. Formerly a non-glistening, whitish, and thickened bladder gave the signal for ectomy; a shining, bluish soft gallbladder was left in place. To-day, the color of the wall, whether bluish, pink, or white, its reflex and softness are no longer determining factors for attack or non-interference. The *quality of the bile* determined systematically, with the help of the duodenal tube, *previous* to operation, and the condition of the bile aspirated from the gallbladder *during* the operation, guide the surgeon in his decision of where to incise and what to incise. W. M.

ALLERGY, ANAPHYLAXIS, AND IMMUNITY IN HAY FEVER AND ASTHMA.

By WILLIAM SCHEPPEGRELL, A.M., M.D.,

NEW ORLEANS, LA.

PRESIDENT, AMERICAN HAYFEVER PREVENTION ASSOCIATION; EX-PRESIDENT, AMERICAN ACADEMY OF OPHTHALMOLOGY AND OTOLARYNGOLOGY; CHIEF OF HAYFEVER CLINIC, CHARITY HOSPITAL.

Necessity of a Working Formula.—There are many theories concerning the subjects of immunity, allergy, and anaphylaxis which are of great importance, but whose final decision may be deferred for a long period. As the object of the American Hayfever Prevention Association is to give the most benefit to hayfever sufferers, both as regards the prevention of the disease by legislative and educational methods in reducing the hayfever weeds,[1] and by developing and encouraging therapeutic methods for its relief, we have accepted certain provisional theories on this subject in the laboratories of the association. This does not indicate that we have ceased our work in immunological research, but simply that a working formula is necessary in order to give the most benefit in the present state of our knowledge.

We have, therefore, accepted "allergy" in hayfever and hayfever asthma as indicating the form of hypersensitivity to the inhalation of pollen protein that is congenital, and "anaphylaxis" as the sensitization of an allergic subject resulting from an exposure to pollen protein in excess of his inherited resistance.

Influence of Heredity.—The influence of heredity in hay fever is shown by the fact that in a series of over 1,000 cases treated in the Hay Fever Clinic of the Charity Hospital and in private practice, over one-third (358) had relatives of the first degree (parents, sisters, or brothers) who suffered from hay fever. The influence of heredity, however, is greater than this, as many cases of hayfever are not recognized, being classed as "summer colds." Allergy may also exist indefinitely without developing hay fever, by reason of insufficient exposure to the hay fever pollens to cause the anaphylaxis necessary to produce the hay fever symptoms.

Importance in Treatment.—In the immunizing treatment of hay fever and hay fever asthma,[2] the recognition of the difference between allergy and anaphylaxis is important. In successful immunization, absolute immunity is not established, but usually a restoration to the congenital allergic condition before the special sensitization which resulted in the hay fever symptoms. Successfully immunized subjects should therefore be warned against excessive exposures to the hay fever pollens to which they are sensitive, as this might result in a renewed sensitization and necessitate a repetition of the immunizing treatment. The failure to observe this precaution is responsible for many cases of relapse after an apparent cure lasting for several seasons.

The following is one of many cases illustrating this statement. One of our patients lived for forty-two years in New Orleans without developing hay fever. Five years ago he visited Tennessee during the month of September, where the atmospheric ragweed pollens are twice as numerous as they are in New Orleans. He developed a severe attack of hay fever, with regular annual recurrences in New Orleans. After two courses of immunizing treatment, he no longer had attacks in New Orleans, but again developed hay fever in Tennessee last September, with probability of recurrence in New Orleans this fall, unless prevented by prophylactic immunizing treatment.

In this case the allergic condition of the patient was not sufficient to develop hay fever from the pollens in New Orleans until the excessive exposure in Tennessee gave rise to an anaphylaxis, which lowered his resistance to the inhalation of pollen protein so that the pollens in New Orleans, which previously had caused no reactions were sufficient to develop the usual symptoms.

Absolute and Relative Immunity.—The question of whether absolute immunity to the pollen proteins exists is important, in order to determine whether every one is liable to contract hay fever under sufficient exposure to hay fever pollens.[3] One difficulty in deciding this from clinical evidence is that, in spite of the greater general knowledge of hay fever, there are still many cases that are classed under the general name of "colds," and the hay fever is not recognized. In northwestern North Carolina, for instance, where "hay fever" as such is unknown among the natives, it is not uncommon to have the laborers develop a "cold"—typical hay fever—when stripping corn in September while surrounded by pollinating ragweed.

On the other hand, one of the members of our Research Department, in order to test the question of absolute immunity, inhaled pollen directly from a mass of staminating ragweed flowers, so that his nostrils were discolored by the millions of pollens inhaled. The reaction, however, in spite of the excessive exposure, was simply mechanical, resulting in no more reaction than from the inhalation of a similar amount of mineral dust.

Incriminating Pollens of Hay Fever.—The determination of the incriminating pollens of hay fever, which formed the subject of the early work of our Research Department, has already been pro-

ductive of valuable results.' Our statement in 1908 that only atmospheric pollens need be considered in hayfever from a prophylactic and immunological standpoint has been almost unanimously accepted, and has limited the research in hay fever to definite practical limits.

Biological Groups of Pollens.—Through the cooperation of the Botanical Department of our association, representing botanical authorities in almost every state, we have been enabled to test hundreds of samples of pollen and eventually to reduce them biologically to a small number of groups. In the immunizing treatment, were it necessary to immunize the patient to each species of plant to whose pollen he is sensitive, it would be a hopeless proposition.[5] In the ragweeds the most common cause of fall hay fever, there are six common varieties, not including the cockle burs, gaertnerias, and marsh elders, which are almost as common in some sections. Of the grasses, the most common cause of spring-summer hay fever, there are hundreds of varieties, and of the wormwoods, which replace the ragweed in the Rocky Mountain and Pacific States, there are over thirty varieties. Fortunately, the pollens of the species of each of these families are biologically similar, and any one, or a combination of several, may therefore be used for testing and for immunizing purposes.

AUDUBON BUILDING.

THE RELATION OF TEETH TO GENERAL MEDICINE.*

BY LOUIS M. GOMPERTZ, M.D.,
NEW HAVEN, CONN.
CLINICAL INSTRUCTOR GASTROINTESTINAL DISEASES, YALE UNIVERSITY.

IT is by no means a recent conception that there is an intimate relationship between diseased teeth and systemic or general disorders, for in the literature of the past few centuries many references to this connection can be found. However, it is only in the last decade that this subject has been accorded the prominence it deserves.

Dr. Benjamin Rush, one of America's most noted physicians and one of the signers of the Declaration of Independence, published his observations in a truly remarkable article commenced in 1801. This, as you will recall, was before the discovery of bacteria and at a time when our knowledge of pathology was only rudimentary, and yet this article, in its essentials is in harmony with our present-day views. Dr. Rush says: "When we consider how often the teeth, when decayed, are exposed to irritation from hot and cold drinks and ailments, from pressure by mastication and from cold air, and how intimate the connection of the mouth is with the whole system, I am disposed to believe that they are often the unsuspected causes of general and particularly nervous diseases. I cannot help thinking that our success in the treatment of all chronic diseases would be very much promoted, by directing our inquiries into the state of the teeth in sick people, and by advising their extraction in every case in which they are decayed. I have been made happy by discovering that I have only added to the observations of other physicians in pointing out a connection between the extraction of decayed and diseased teeth and the care of general diseases."

Our interest in the teeth begins at birth. The appearance of baby's first tooth marks an epoch in the family life, and when it comes, the anxiety of the fond mother is relieved and the pride of the doting father is most pronounced when he exhibits the tooth for general inspection and admiration.

At a very early period in the child's life the question of diet becomes most important, because of its direct connection with the growth of the permanent teeth, and if this diet is deficient in certain essentials, early decay of the teeth soon becomes evident. Zilva and Wells of London have shown experimentally that the teeth are very early affected by scorbutic causes. Damage may be found in the teeth even before any general symptoms can be detected. It is not at all unlikely that defects in the teeth arise owing to faulty diets that are not clearly recognized beforehand. Hess of New York maintains that children not infrequently suffer from a "latent scurvy" which is really a condition of malnutrition; and this frequently cannot be diagnosed until an improvement in the malnutrition is brought about by the administration of an antiscorbutic. Since these unrecognized conditions, though present in many cases, are frequently overlooked by the doctor, they may help to explain the hitherto unexplained prevalence of tooth decay.

It has been pointed out that diet plays an important part in the growth and nutrition of the child, for example. A child's diet is most likely to be deficient in the fat-soluble vitamine from the ninth month to the second year, and if this is so, the condition known as rickets may make its appearance. The permanent teeth calcifying at this period are, as you know, the incisors, canines, and first molars, and it is just these teeth in children that are most commonly hypoplastic and carious.

The average diet, particularly that of the poor, is now more than ever made up of specially prepared cereals such as rice, wheat, oats, etc. Meats and the animal fats tend to play a smaller part. Vegetable fats, in the form of oleomargarine, etc., are superseding butter; whole milk is being more and more excluded from the diet of the needy, partly because of the expense and partly because of a curious antipathy that many people have toward it. Obviously, such a dietary is very deficient in the fat-soluble vitamine. Here presents itself a picture rather obscure but none the less real, illustrating, in part, the cause of defective teeth in our own time.

Following this same line of reasoning, one can

*Read before the New Haven Dental Association, April 7, 1920.

also understand why the Esquimaux in their own country, where the flesh and blubber are the staple articles of diet, have such excellent teeth, while the inhabitants of Chile, who live chiefly on cereals, have teeth which are much less sound.

Having seen that early decay is due more or less to an improper dietary, we must bear in mind that this condition is carried over into adolescent and adult life, and now comes the added damage from bacterial invasion which supersedes the early decay in importance and becomes a menace to the general health of the individual. It is a well known fact that the mouth is an ideal place for bacterial life, and even though there are no lesions of the teeth or gums, any number of pathogenic and saprophytic bacteria may be present. The most infectious lesions of the teeth may be caused by any of a large number of pyogenic bacteria, and secondary invasion of saprophytes is the rule rather than the exception.

Originally the bacteria of the mouth were studied with the theory that one variety or group of bacteria was the etiological agent of a definite lesion, but so far as I know, no one has been able to demonstrate specific organisms in the various diseased conditions. Any one of the pyogenic bacteria may cause an alveolar abscess or a pus pocket at the gingival margin. We almost always find a mixed infection with a great variety of combinations.

Although pyorrhea is mentioned as a possible causative agent of many general diseases, it is my belief that apical abscesses are of greater pathological import. In pyorrhea drainage is often good, while alveolar abscesses lack drainage and are also subjected to pressure, which adds to their virulence. Septic foci in the gums have room for expansion, whereas abscesses localized in bony tissues are more liable to invade the blood stream. And lastly, pyorrhea often gives rise to symptoms and signs which attract the attention of both patient and dentist, whereas alveolar abscesses do not, as a rule, give rise to a single disagreeable symptom by which one may suspect their existence. This last is quite evident, since as you all know, the frequence of apical abscesses has only recently been proven by means of systematic dental radiography. Black in a recent article reports abscesses at the roots of 47 per cent. of devitalized teeth.

An ingenious conception of infections and diseases caused by streptococci has been suggested by Rosenow, Billings, and their coworkers. They conclude from their observations that members of the streptococcus-pneumococcus group may develop affinity for certain tissue not only while growing in these particular tissues, but also while growing in the primary foci of infections. This they call the organotropic tendency of these bacteria. The interesting deduction is made by Rosenow that bacteria growing in a given tissue acquire an affinity for that particular tissue. There is little tendency to involve any other kind of tissue. Therefore he claims that a focus in a specialized tissue is of less importance as a distributor of bacteria than the primary focus.

It is extremely important that conclusions so interesting and of such a vital and fundamental nature be confirmed by other observers and that their full acceptance await repeated verification.

The underlying causes of dental caries are still unknown. They have usually been sought in local bacterial conditions within the mouth, if one may conclude from the emphasis that dentists place on oral hygiene. They do not seem to realize that the presence of bacteria in itself never causes disease. Evidently much depends on our theories of resistance.

The bacteria may reach various parts of the body through different channels where they may cause disease. The distribution of the infection in oral focal disease may take place by continuity where the surrounding structure may become contaminated from infectious material about the teeth. By direct infection, for example, pyogenic organisms from dental sepsis may and probably often do spread and produce tonsillitis, pharyngitis, and inflammatory conditions of the surrounding tissues. Other modes of distribution have been described, namely, infection through the gastrointestinal tract, through the lymph glands, and through the circulation.

In regard to teeth and their relation to systemic disturbances it is admitted that many infectious diseases, such as infectious arthritis, acute nephritis, and bacterial endocarditis, may at times be traced to septic foci in the mouth, just as they are often attributable to foci in the tonsils or any part of the organism.

A writer, supposedly an authority on the subject, enumerates twenty-six distinct diseases that he positively states may arise from dental lesions, and he goes on to say, to quote his own words, "Neither have I presumed, in compiling this list, to collect all the claims that have been made, but have aimed to be conservative." In this list he has named such disorders as gastritis, appendicitis, colitis, gastric and duodenal ulcer, nervous and mental conditions, especially in children. It must be obvious that the enthusiastic and sanguine reports made by some of the medical fraternity as well as the dentists often border on the absurd. The claims often made by these enthusiasts as to the relation of gastrointestinal disorders and oral sepsis are that the septic material, after being swallowed, sets up an inflammation in the various parts of the gastrointestinal tract, and as a result there are produced gastritis, enteritis, colitis, appendicitis, cholecystitis, and even gastric and duodenal ulcer.

I believe that it is not unlikely that the swallowing of poorly masticated food, and of pus, putrid material, etc., has some slight influence upon digestion. It does not seem probable, however, that it has an important bearing on many general disorders for which the teeth are now believed to be more or less responsible. The fact is the normal mucous membrane of the stomach is capable of tolerating a great deal of abuse. It can take care of poorly masticated food and by means of its germicidal acids destroy septic material when swallowed. The deleterious effects of oral sepsis seldom go through this channel, although many have expressed views to the contrary.

It doesn't matter where the infection is situated, in the mouth or in any other part of the body, such infection should be eradicated as efficiently as possible. However, the many glowing promises often made by physicians as well as the dentist that the

extraction of poor and infected teeth will prove a panacea for all ills should be condemned. Perhaps you think I am unnecessarily severe in my condemnation of physicians who claim "cures" for all the "ills that flesh is heir to" through the medium of the teeth. You would not think so if you listened to the tales of gastric disturbances from the "toothless" army of unfortunates who invade the physician's offices daily and are unable to eat, because some physician, in cooperation with the dentist, promised magical results; such as the disappearance of a gastric or duodenal ulcer, the fading away of a goiter, yes, and even promising to restore lost manhood, if they would only submit to the extraction of a few offending teeth. I could name many physicians who have made these promises. And as for the dentists, listen to the words of one of your profession. In an article in *Modern Medicine* of 1920, among other things, Dr. C. B. Bray says: "But it is with the workman himself where the really big thing is accomplished by the industrial dentist. He has come to seem almost like the mythical healer of ancient days. His operations are confined to the teeth, but he secures astounding results in almost any part of the anatomy. Men come to him with a chronic case of rheumatism. He pulls a tooth—Presto! the rheumatism which may have been in the man's ankle at the other end of his anatomy is gone. From a makeshift, inefficient, dissatisfied, grumbling workman, the patient has been transformed into a healthy, efficient workman who goes about his duties with a song. All by the pulling of a tooth. But this is only one case. There are hundreds. Men come with indigestion-bad teeth. Men come with neuralgic pains; in fact, with everything down to and including an ingrown and souring disposition, and the dentist fixes them up by treating their teeth. Is it any wonder dentistry is being hailed with loud acclaim in industry?"

I believe that the *x*-ray is more or less responsible for the fad of "tooth pulling contests" which are now taking place throughout the country. The use of the *x*-ray in dentistry is undoubtedly a valuable aid in diagnosis, but the liability to err in interpreting the findings must be evident to all. I can recall many individuals who have had normal teeth extracted because the *x*-ray showed—or rather the roentgenologist said they showed—disease. I could also relate a number of cases where a variety of diseased conditions at the roots of teeth have been correctly diagnosed through the medium of the *x*-ray. Clinical experience, however, shows these same individuals living peaceful and healthful lives in spite of the fact that they have refused to have their teeth extracted.

I never fail to examine the mouth of every patient who comes to me for relief, and I want to emphasize the fact that I have seen a large number of digestive disturbances and other diseases due to dirty mouths and diseased teeth. But I have also observed many individuals whose digestive apparatus has been seriously impaired by the ruthless, careless, and unnecessary extraction of teeth. The interference with digestion, the improper mastication of food, the kind of food that the toothless patient must necessarily take, thus seriously interfering with nutrition, should all be taken into consideration before we advise the removal of teeth, which I consider a serious matter.

In conclusion I wish to make a plea for a commonsense, conscientious, conservative co-operation between the dentist and the physician. At the present time we are passing through an era, so common after important medical theories or discoveries, of permitting the pendulum to swing too far and allowing our enthusiasm to interfere with good judgment. There is no question that oral sepsis bears a definite and often vital relationship to systemic disease, but to accuse the teeth of everything from ulcer of the stomach to a sour disposition is not rational. When team work is established between the physician and the dentist better results will be achieved.

STUDY OF MAN AFTER DEATH.

BY ARTHUR MACDONALD, ANTHROPOLOGIST.

WASHINGTON, D. C.

IT has been said that few men can be estimated justly as to their ability and worth, until after they are dead. Psychologically this is probably true, and in the great future it may also become physically true when scientific research on the human body, especially brain and nervous system, has made sufficient advancement.

There may come a day, for instance, when further microscopic and chemical development in the investigation of the brain will establish correlations between a refined analysis of brain cells and the mentality of the person to whom the brain once belonged.

The Human Body Must Be Studied as One Whole After Death.—The methods of approaching the study of man after death are in need of much im-

provement. The idea is too often to procure material for some special or minor investigations, which are liable to be very limited. From the scientific point of view, requiring broader interpretations, we must study the human body as a whole and the relation of its various parts to one another in their biological and anthropological unity. Here pathology should take a subordinate place. It is due time that after death as before death we give more attention to the normal and super-normal man, rather than the pathological or abnormal man; in short, to the successful, talented and genius man rather than the unsuccessful, criminal and insane man.

Three General Causes of Death.—The study of man after death should include all the important parts of the body. Most of the lesions found are the marks of disease, rather than the cause of death. It is not known how great a degree of many diseases is necessary to cause death, for one patient may recover with a lesion sufficient to destroy another. The brain and the heart are organs especially capable of giving symptoms during life without corresponding lesions after death. Every death may be attributed to one of three causes: (1) interference with respiration (asphyxia or apnea), (2) interference with the heart's action (syncope), and (3) interference with the nervous system (coma or shock). The number of distinct diseases producing death is limited.

Necessary to Know Causes of Disproportion of Organs.—The size of an organ naturally depends upon the size and weight of the body.[1] The interpretation of weight and dimensions of organs has hardly begun to be recognized. When there is disproportion in any organ it is desirable to know whether it is due to type, development, habit, condition or disease. But there is no standard as yet for comparison. The insurance companies have given tables for body weight and height, which are valuable.

Approximate weights of organs of adults with their percentages in relation to the weight of the body are given in table 1.

TABLE I.

APPROXIMATE WEIGHTS OF ORGANS IN AN ADULT.

	Grains.	Ounces.	Percentage Relation to Body Weight
Brain	1,400	49	2.37
Heart	300	10	0.46
Lungs	1,175	41	2.0
Thymus gland	5	0.13	0.0086
Spleen	170	6	0.346
Liver	1,600	57	2.75
Pancreas	200	7	0.346
Kidneys	300	10.5	0.44
Testicles	48	1.5	0.12
Ovaries	14	0.5	0.04
Adrenals	10	0.35	0.014
Muscles	30,000	1,050	43.09
Skeleton	11,500	400	15.35

To secure a conception of the value of an organ we must compare its size, shape, volume and weight and the proportion of parenchyma to skeleton tissue and included fat, blood and other fluids.

Statistical Study of Human Viscera Necessary.—The object of the statistical study of human viscera is to record results comparable with many investigations of anthropologists dealing with other organs or dimensions, and also to provide materials for investigation of changes caused by disease in the absolute measures and interrelations of the organs. It has been found that the more healthy organs are accompanied by higher correlation and less variation.

It is also known that age alone is not sensibly correlated with the weight of the viscera. The healthy heart, for instance, is smaller than the diseased heart, and sickness increases with age; so that if the weight of heart increases with age, it is what might be expected.

Correlation of Weights of Human Viscera.—There is need of a systematic collection on a large scale of normal and pathological data as to the human viscera. Even with the meager material on hand, there are sensible, though moderate correlations between the weights of the heart, liver, spleen and kidneys. From Table 2 it appears that the heart-kidney correlation is higher than the heart with the liver or spleen.

TABLE II.

CORRELATIONS OF HUMAN VISCERIA.

Correlation of heart and liver is	0.2780 ± 0.0329
Correlation of heart and spleen	0.2654 ± 0.0276
Correlation of heart and kidneys	0.4004 ± 0.0279

It has been found that the weight of the heart may be predicted from the weight of the body and kidneys with an average error of about 8 per cent. of the mean weight of the heart.

The Skeleton.—Some physical characteristics are organic and are to be studied on the skeleton and dead body; others are physiological and to be investigated on the living. But the skeleton ranks first, for it determines the general form of the body; it is the foundation of its physical superstructure.

Knowledge of Skeleton and Viscera Necessary to Study Brain.—Since, as we shall see, stature, nationalty, race, body weight, build and viscera seem to be related to brain weight, all these data should be determined in each case. The skeleton therefore should be preserved and mounted to be examined along with the brain and other viscera. One of the difficulties of otherwise careful studies of the brain is the omission of cognate material which might prove to be of great value, since without it, such study may be reduced in its significance, owing to want of confirmation by collateral evidence and correlations.

Skull the Great Document of Prehistoric Man.—The skull is formed by three modified vertebrae and is the real commencement of the vertebral column. It is because of the brain that the skull, which encases it, receives so much attention. The skull also is one of the parts of the skeleton and of the entire body, which exhibits the greatest number of well marked variations. The difference in the form and the dimensions of the skull in correlation with those of the brain and masticatory organs serves to distinguish races and species.

The skull with the rest of the skeleton is the only anatomical document of prehistoric man which has come down to us; it is only in studying skulls that we can connect and compare extinct races of mankind. Thus, the mean cranial capacity of the Australian is 79 cubic inches, the African 85 and the European 91 (Flower.)

The smallest adult human cranium has a capacity of 63 cubic inches, while the largest gorilla cranium has 34 cubic inches. It appears from a study of

the very earliest skulls that the vertical diameter was small, making the brain flat, indicating that the grain grew in length and breadth before reaching its present stage in height.

The American Indians have a low cranial capacity, which increases in the yellow races until it attains its maximum in the white race; it appears to vary somewhat according to intellectual endowment.

In general, sutures in the skulls of Europeans are more tortuous than in those of primitive peoples; the metopic suture becomes obliterated in 90 per cent of adults. The skulls of women in prehistoric times, as compared with those of men, are larger than at the present time.

Cranial Capacity Increases From Barbarism to Civilization.—As will be found in Table III, all European nations have a cranial capacity more than 1,400 cubic centimeters. In general, the table shows that as we advance from barbarism to civilization, the cranial capacity also increases.

The close correlation of cranial capacity with weight of brain makes it probable that brain weight also increases as we pass from barbarism to civilization.

TABLE III.

CRANIAL CAPACITY.

Races and Nations.	No. of Skulls	Vol. in Cu. Centimeters
Australians	8	1,228
Hottentots	3	1,233
Peruvians	152	1,233
Americans	341	1,315
Negroes born in America	12	1,323
Mexicans	25	1,338
Negroes (in general)	76	1,347
Negroes born in America	64	1,371
Wild Indians	164	1,376
Parisians (common)	35	1,403
Parisians (Cemetery of ———)	117	1,409
Parisians of 12th Century	115	1,425
Germans	30	1,448
Parisians of 18th Century	125	1,461
Anglo-Americans	7	1,474
Parisians (private graves)	90	1,484
Germans in general	38	1,534
English	6	1,572

Not being able to obtain the direct weights of the brain in sufficient numbers in the various races, we must take the cranial capacity as a general index of the weight of brain.

Geography of Cephalic Index.—Dolicocephaly is almost exclusively located in Melanesia, Australia, India and Africa; subdolicocephaly is found in North and South of Europe, but is met with only sporadically in other parts of the world. Mesocephaly is frequent in Europe, Asia and America. Brachycephaly is limited to Western and Central Europe and some populations of Asia. The ancient fossil skulls are dolicocephalic, the negro races are generally very dolicocephalic, but the greater number of the Mongol races are brachycephalic. The inferior races are mostly dolicocephalic.

The cephalic index may vary in one and the same race to 10 per cent., but when it reaches 15 to 18 per cent., it is due to mixture of race.

The skulls of Parisians of the 19th century are more capacious than those of the 12th century.

Neanderthal Skulls Probably the Oldest.—Human paleontology begins with the Post-pliocene or Mammoth epoch. The Neanderthal skull is one of the oldest; it is like the valvarium of the female gorilla; the superciliary arches are altogether Simian, but the skull is undoubtedly human, having a capacity of 1,200 cubic centimeters. This skull may represent an inferior race, that has disappeared and probably existed at a prodigiously remote period.

Solution of Some Craniological Problems.—It has been found possible to estimate the capacity of the human skull, when this cannot be measured directly. This is done with a mean error of 3 to 4 per cent.[1] It is possible to find the mean skull capacity of a race without the use of sand seed or shot to a degree of accuracy comparable with that of the direct method owing to the personal equation of the measures even when using the same method of direct determination. The determination of the skull capacity of living individuals can be found with a degree of accuracy sufficient to determine whether skull capacity is or is not closely correlated with intellectual power. Thus, craniometry must tabulate means, variables, correlations, and their probable errors in order to draw safe inference and make racial comparisons.

The cephalic index of the cranium + 2 units, will correspond to the cephalic index on the living subject, to whom the skull belonged; two units are subtracted from the cephalic index on the living to obtain that on the cranium; the muscles of the temporal region are thicker than those of the frontal or supraorbital areas.

The age of a cranium is determined according to the number of pieces composing the cranium, their position, structure and conformation also by the obliteration of sutures and the order in which the obliteration of each suture takes place; by the general form of the forehead and the angle of the lower face, when all the dimensions of the skull and the status of dentition are noted.

Some Racial Anomalies of the Skull.—The differences in the form and the dimensions of the skull in correlation with those of the brain serve to distinguish races and species. Thus the Inka bone (one of the wormian bones), between the parietal and occipital bones, is frequent in Peruvian crania —20 times in 100; in negroes 6 times; in Europeans it is still more rare; among Indians of Arizona this bone is more frequent than among Peruvians. The suture of the malar bone is peculiar to Japanese crania—25 to 40 per cent., and only 9 per cent in European races.

Height.—Some facts as to height will be useful to recall in the study of man after death. The length of the humerus multiplied by 5.06, or the length of the femur multiplied by 3.66, equals the height of the man. Thus the height of prehistoric peoples can be worked out.

In height man may vary from 1 m. 25 (4 feet 1 inch) to 1 m. 99 (6 feet 6¾ inches). Below 1 m. 25 man is abnormal or pathological (dwarfism); above 2 meters man is also abnormal (giantism). Both these extremes are sterile. The extreme averages of different populations run from 1 m. 38 (4 feet 6 inches) to 1 m. 79 (5 feet 10.5 inches); the Scots of Galloway,[2] or Scots of the North are 1 m. 78. The stature of man is not more than 2 or 3 centimeters higher than his skeleton.

The length of the trunk in man is more than one-third and less than two-fifths of the height. The arm reach in American soldiers is as 1,043 to 1,000.

Thus it appears that the height of an individual is closely related to the weight of the cerebrum and that brain lesions are often associated with dwarfism.

The Great Difference Between Man and Animal Lies in the Brain.—In all the principles of internal structure, in the composition and function of parts, man is but an animal. It is remarkable that beings should exist so near to each other in their *physical* structure and so wide apart in their endowments and capabilities.

The comparison of the brains of animals brings into view the immense difference between the small smooth brain of a fish and the large and developed brain of man, which is the organ of his thought. The brains of the higher apes are much less complex in their convolutions and much less in both relative and absolute weight. The gorilla's brain barely exceeds 20 ounces in weight, while man's brain hardly weighs less than 32 ounces, though the gorilla's body is considerably larger.

This great difference between man and animal in brain weight is confirmed by a similar difference of cranial capacity which is indicated in Table IV, where it will be seen that the cranial capacity of man is about three times as great as that of the animals nearest to him. It will be noted also, starting with the Newfoundland dog, that the cranial

TABLE IV.

CRANIAL CAPACITY (TOPINARD) IN CUBIC CENTIMETERS.

Man, European male	1,500
16 Gorillas, males	531
3 Orangs, males	439
7 Chimpanzees, males	421
2 Lions,	321
1 Bear	265
1 Newfoundland dog	105

capacity of the animals gradually increases until it reaches man, when there is a great and sudden increase. Likewise as to arm reach, in American soldiers, the arm reach is to the height as 1,043 to 1,001; in the gorilla it is as 1,654 to 1,000, showing a great difference from man. In Sweden the average height is 8 per cent. less than the average arm-reach[4] in soldiers.

Weight and Volume of Brain and Intellectual Activity.—From 11,000 brains weighed, Topinard finds an average weight of 1,361 grains for man and 1,290 grains for woman. The mean weight of the largest brains in Europe is 1,417 grains, taken from 157 brains of the Scots[5] (Reid and Peacock).

The grey substance represents 37 to 38 per cent. of the total weight of the brain. As the thickness of the grey matter is very much the same in all brains the complexity in structure of the convolutions corresponds to the increase of the grey substance and probably of the psychic force. The grey substance is the part exclusively belonging to the mental processes.

Intellectual Activity Probably Increases Size and Quality of Brain.—It is probable that the density of the cerebral substance increases as well as the total volume and richness of convolutions by intellectual activity. The more work a limb or organ of a body does, the more it increases in size, so it is probable that the more the brain works the more it increases beyond its ordinary term of growth and the time for the closing of the sutures is also increased.

If the average man's brain has 100 or more connections for every fact which he remembers, the number of such connections in the brain of the intellectually superior man is probably many times greater. It seems likely, therefore, that an elaboration of brain structure would accompany the higher intelligence.

The Higher the Social Status the Greater the Brain Weight.—As Table V shows, the study of the brains of distinguished personalities has made a beginning. As an illustration of this, it may be of interest to note a few results.

Table V gives the average brain weights of 255 persons[6] according to the nature of their occupation. It will be seen that as the intellectual status of the occupation increases the average brain weight increases. Though the numbers are not large, yet they are sufficient to create a probability of such tendency.

TABLE V.

BRAIN WEIGHT AND OCCUPATION.

Occupation.	Number.	Brain Weight in Grains.
Unskilled laborers	14	1,410
Skilled laborers	34	1,433
House servants	14	1,435
Expert workers	123	1,449
Mental workers	28	1,468
Professional workers	22	1,500

It appears from studies of thousands of brains of all social and intellectual classes that men who never remain employed, often unable to learn a trade, stand lowest in scale of brain weights; then come in rising order mechanics, clerks, business men and teachers in the elementary schools. The highest in brain weight are individuals with marked mental ability as artists, mathematicians, scholars, and statesmen. Also the more numerous, the more sinuous and the more ramified the brain fissures, the greater is the degree of expansion of the cerebral cortex. Vigorous minds possess superior brain organization (Spitzka). The brain of Gauss, the mathematician, for instance, is as far removed from that of the average as the savage is removed from the brain of the nearest ape. These differences usually extend to the weight of brain.

TABLE VI.

DISTINGUISHED PERSONS.

Categories.	Number.	Averages.	Average Brain Weight.
Scientists	57	64.7	1,467.1
Artists and Philosophers	24	57.6	1,479.0
Men of Action	23	61.0	1,516.3
Total and Averages	104	62.3	1,439.3

In Table VI the cases are divided into scientists, philosophers and artists, and men of action as government officials, statesmen, lawyers, and military men. Assuming that intellectual status is reflected in mass and weight of brain in a general way, it will be seen that men of action will average the highest in brain weight.

High Correlation Between Brain Weight and Cranial Capacity.—It has been found that with the exception of cranial capacity, all skull characters are about half as variable as brain weight. The agreement in variability between cranial capacity and brain weight is expected on theoretical grounds alone; and when in practice it turns out to be very close, this gives a general trustworthiness of brain weight statistics. Brain weight has been estimated from cranial capacity. Welcker found an

average coefficient of 0.93. More recent studies have lessened the coefficient. Manouvrier has a good working coefficient of 0.87.

TABLE VII.

BRAIN AND NATIONALITY OF DISTINGUISHED MEN.

Nationalities	Numbers.	Average Weight of Brain.
Americans (including Canadians)	27	1,519
British (including Scots)	14	1,481
Frenchmen	20	1,456
Germans and Austrians	38	1,439

Table VII shows the average weight of brain of American, British, French, German, and Austrian distinguished modern men. The Americans and British show the highest average brain weight.

Ratios Between Large and Small Brain.—The cerebrocerebellar ratio is the weight of the cerebrum as compared with that of the cerebellum, the latter being unity. This ratio is for distinguished men from 1.90 down to 1.80, while the ratio of the average man is 1.77 down to 1.70; that is the ratio is fully a unit higher in eminent men; in other words, the cerebrum or thought apparatus is relatively larger, while the organ of motor coordination (cerebellum) remains relatively reduced.

Exceptions to the Rule Often Due to Pathology.—Quite a number of heavy brains are found in idiots, imbeciles, criminals, insane, and other defectives; also certain laborers have large brains. These facts sometimes are used as an argument against the relation of large brains to superior minds. But these cases are almost always explained by pathological hypertrophy, sometimes shown by grave defects in structure, as diminution in ganglion cells, etc. Age and nature of disease causing death also affect the weight of the brain.

Correlation of Brain-Weight with Other Characteristics.—The degree of correlation of brain-weight with other characters of the body makes possible suitable corrections for bodily differences, as will make feasible any comparison of the brain-weights of different races, or different groups of the same race.[6] This gain shows the importance of preserving the skeleton and viscera in connection with the study of the brain. It has been found that with the exception of capacity, all skull-characters are only about half as variable as brain-weight. So far as investigation has gone (not far as yet), the correlation of brain-weight with age, stature, and body-weight is low. The correlation of brain-weight with skull-length and skull-breadth is, in comparison with other characters, fairly high and for skull-length and breadth positive. There seems to be a steady decrease in brain-weight with advancing age, beginning at about the twentieth year. The correlation of brain-weight with stature and with body-weight is positive. The diminution in brain-weight follows very closely the diminution in the size of the head.[7] While the size of the head increases with stature, it does not increase as fast as stature.

One of the main objects in the study of the relation of the brains to the size of the head is to be able from certain chief measurements of the head to predict within the limit of normal variation the approximate weight of the brain. Thus the probable brain weight of an individual can be determined from stature, age, diametral product and horizontal circumference with a mean error of about 50 grams. The mean deviation in brain weight from the mean of the groups is about 80 grams. That is, we improve the prediction in the ratio of 8 to 5 by taking into account these characters.[8]

Physical Degeneration May Influence Intelligence.—Physical stigmata of degeneration are more serious in proportion to their fundamentality and number. Excessive asymmetries of the head are abnormalities and generally unfavorable signs as to mental status in two-thirds of the cases. The eyes can be too close together (simian) or too far apart (cretin). An imperfect development of the socket of the eye, on account of its close anatomical connection with the brain, may have a concomitant, if not causal, relation to cerebral troubles. Want of development, or excessive development of the bony frame of the nose, are stigmata of degeneration, causing troubles of breathing, influencing the power of attention, and through this the intelligence.

The Future of Nature Points to Cerebral Specialization.—A general conclusion of human morphology is that cerebral specialization on the part of nature is the prime factor in the future as in the past, and is ultimately dependent upon hygienic conditions, which require proper reactions between the vascular, nervous, and other systems. This necessary physiological equilibrium depends upon the adequate exercise of its functions by each system of tissues involved.

What Persons Should Be Studied After Death.—In pioneer work, to which the extensive study of persons after death belongs, it may be necessary to limit greatly the number of cases at first, for there are so few specialists working at this most difficult task. All persons of genius, talent, or special ability perhaps should be selected first. Then come those who have been thoroughly educated, though they may not have either genius, talent, or great ability. Eventually every representative of the many types of men, from the lowest idiocy to the highest genius should be studied after death.

What Parts of the Body Should Be Preserved for Study After Death.—Inasmuch as the results of study of man after death are comparatively very meager, and since very little has been determined, it is best, as in all original work, to have too much rather than too little material, for it might turn out as sometimes happens in new work, that things omitted at first have subsequently proved to be of much value. Owing to inadequate knowledge, it is best to take the safe side. I would, therefore, suggest as a minimum that the following parts of the body be preserved: Brain, skeleton, lungs, stomach, kidneys, liver, and whatever other parts specialists consider important. Whatever material is preserved should be permanently preserved as far as possible, so if not studied at first, it may be accessible to investigation later.

History of the Study of Brains.—Individuals have now and then directed their relatives to arrange to preserve their brains after death. There was founded in 1881 the Mutual Autopsy Society of Paris, for securing elite brains for scientific study. In the United States the pioneer in such effort was the American Anthropometric Society of Philadelphia, established in 1889, followed by the Cornell Brain Association, directed by Professor Burt G. Wiler.[9] Later, Retzius, a Swedish anthro-

pologist, and Tigerstedt, a physiologist, proposed that their colleagues bequeath their brains for purposes of scientific investigation.

Americans Whose Brains Have Been Studied.—Among Americans whose brains have been studied are Hon. Charles G. Atherton,[10] a United States Senator (1854); Abraham Lincoln (1865); Louis Agassiz (1873), a naturalist; Chauncey Wright (1875), philosophical writer; Philip A. Aylett (1878), a blind physician; Edward Seguin (1880), a French-American physician; E. H. Knight (1883), a mechanician; Edward Olney (1887), mathematician; A. Thorndyk Rice (1889), diplomat and journalist; B. G. Ferris (1891), jurist; Benjamin F. Butler (1892), soldier, lawyer, and statesman; Hosea Curtis (1893), mathematician and educator; Walt Whitman (1893), poet; Garrick Mallery 1894), ethnologist; James E. Oliver (1895), mathematician; George McKnight (1877), physician; Caroline B. Winslow (1896), a physician, the only American woman whose brain has been studied; Edward Charles Seguin (1898), physician; Frank Collier (1901), lawyer; Henry Wilson (1902), Vice-President of the United States; John W. Powell (1902), ethnologist and geologist; James B. Pound (1903), lecturer, manager, and soldier; George Francis Train (1904), merchant and traveler; Alexander Winchell (1904), geologist and educator; Samuel D. Gross (1905), physician; Isaac J. Wistar (1905), scientist and philanthropist; W. J. McGee (1912) (death mask made), ethnologist (the results of the study of his brain have not at this writing been given).

Dedication of Our Bodies to Science Increases Future Usefulness.—The author has signed over to science his body, including skeleton and viscera, as well as brain, for reasons already advanced in this article, and he would urge all persons to be willing to do likewise, especially those who have had the advantage of higher education and professional careers.

If we had knowledge of the bodies of our ancestors, including their ages at death and their different diseases; if also their physical measurements, color of hair, eyes, and skin were known; if, in brief, we were in possession of adequate knowledge of the physical nature of our ancestors before and after death, then we would know better how to protect ourselves from the physical weaknesses to which we are most susceptible. If, in addition to this, we knew the mental and moral characteristics of our ancestors as well as their physical, then we would be following the maxim, "know thyself." Such knowledge would be power, enabling us to live more rational, useful, and truly happier lives, with less solicitude for personal enjoyment and more willingness to make sacrifices.

Just as we are benefited by knowledge of our ancestors, from whom we have received most of what we are, so we in turn should make our ancestorship beneficial to future generations.

THE BORDEAUX CONCEPTION OF LETHARGIC ENCEPHALITIS OR EPIDEMIC ENCEPHALOMYELITIS.

BY RENÉ CRUCHET, M.D.,

BORDEAUX, FRANCE.

PROFESSEUR AGRÉGÉ Á LA FACULTÉ DE MÉDECINE DE BORDEAUX; MÉDECIN DE L'HÔPITAL ST. ANDRÉ.

FROM September to the end of December, 1915, while I was in Commercy, then at Verdun from December to the middle of February, 1916, and, finally, at Bar-le-Duc, centers of military sanitary service, where I had the direction of the Neuropsychiatric Service, I had remarked the great frequency of cases of encephalomyelitis of a type different from the ordinary. In April, 1917, therefore, before Von Economo and Netter, working with Moutier and Calmette, I was able to study forty of these cases. The description which I then published of these cases under the title of "Subacute Encephalomyelitis" was identical with the syndrome since described under the name lethargic encephalitis. The following is what I wrote at that time:

"From the first it has been quite easy to diagnose the cerebello-protuberantial, cerebello-bulbar, or medullary lesions, but it was necessary to exclude in succession the hypotheses of hemorrhage or softening of a tumor, of diabetes or uremia, of tuberculosis or syphilis, and the same with regard to the central lesions denominated polioencephalitic, studied by Medin and the Americans. One did not meet here with the distinctly epidemic characteristics of violent onset, high fever, vomiting, severe pains, wide extension of paralytic troubles, subsequently limited to certain muscle groups, and more or less considerable ensuing atrophy. In many cases with a moderate febrile reaction one might question whether one had not to do with some typhoid or paratyphoid infection running an extremely mild course, but examination of the blood gave no positive result. The hypothesis of an aborted cerebrospinal meningitis was also not tenable for examination of the cerebrospinal fluid, although it often showed a lymphocytic and albuminous reaction, was always negative as regards microorganisms. However, it was difficult not to be struck with a certain family resemblance of the symptoms of these affections. Thus one was led to place them among the central nervous affections of attenuated virulence. Their clinical characteristics generally were the following:

"*Onset.*—At the beginning the patients complained of extreme lassitude, physical and mental debility. They had no violent headache, but complained of a sensation of weight in the head. Fever was usually absent, but occasionally there was a slight elevation of temperature, between 37.5° and 38° C., for a few days. In some cases in which it has been more mild it has seemed rather to have referred to some spinal complication in the clinical course such as hemorrhage or bulbar asphyxia. These patients, aged usually between twenty-five and forty-five years, all presented a dull facies, indifference, semitorpor, and emaciation, with an earthy hue of the skin, sometimes subicteric, and gave the impression of some profound infection or intoxication.

"*Clinical Forms.*—There was a variety of clinical forms which might be grouped as follows:

"1. The mental form in which the cerebellar torpor, anemia, pupillary troubles, trembling, dysarthria, even paraphasia, and the reaction of the cerebrospinal fluid led one to think first of a sort of general paralysis or of some variety of dementia.

"2. The convulsive form in which the attacks simulated an epileptic status, but this was generally only temporary.

"3. The choreic form having all the characteristics of infectious chorea of the adult.

"4. The meningitic form in which the meningeal reactions, rigidity, Kernig's sign, rachialgia, somnolence, and vasomotor phenomena, always associated with profound and lasting encephalitic troubles, could not be explained by any of the known causes.

"5. The hemiplegic, or rather the paretic, form which, in its rapidly progressive course and its arrest at a certain stage of its evolution, was distinctly to be differentiated from the ordinary hemoplegia of the adult.

"6. A pontocerebellar form with ptosis, conjugate paralysis of the eyes, and titubation, and a simple cerebellar form, often giving a deceptive resemblance to the symptomatology of tumor of the cerebellum.

"7. A bulbo-protuberantial form with various nuclear lesions affecting the nerves of this region, the trigeminal, facial, and vagospinal.

"8. An acute ataxic form resembling in certain features toxiinfectious polyneuritis.

"9. An anterior poliomyelitic form, the characteristics of which, at least the initial characteristics, lead on to think of infantile paralysis—an exceptional form, however.

"*Evolution.*—The evolution of these clinical types, often mixed, follows no special course, and in spite of their polymorphism shows a resemblance between the different forms. Except for two cases of death occurring suddenly, one in the course of status and the other from bulbar asphyxia, the convalescence was very tedious, and the asthenic and somnolent patients returned slowly to health and often showed sequels having reference to their anatomical lesions, such as paralysis or spasmodic conditions, cerebral fatigue, muscular atrophy, trembling, etc.

"*Nature.*—The culture and inoculation of the blood into guinea pigs, as also examination of the

cerebrospinal fluid systematically carried out, gave no results. In the case of the patient who died suddenly of bulbar asphyxia, a certain quantity of the region most affected in the bulb was ground up with a cubic centimeter of physiological serum and injected into the brain of a rabbit, but without the slightest result. We were, however, poorly situated to make pathogenic researches, for most of the patients came to us in the stage of full development of the disease, at a time when the infection was declining. Thus many of the symptoms still not well known readily passed unperceived, especially taking into consideration in many cases the slight intensity of certain manifestations and their indefinite character which sometimes suggested merely an exaggerated fatigue or the muscular soreness of over exercise."

Thus ever since my first communication I insisted upon the polymorphism of the disease which recalled in certain of its aspects Medin's disease, but which was to be differentiated from it by the rarity of the medullary localizations and the frequency of encephalic symptoms, the irregularity of the fever which was usually of slight degree, the ordinary absence of pain, and the persistence of cerebral torpor. I also emphasized the dull facies of these patients, their asthenia, their *somnolence*, and mentioned also the lengthy convalescence.

Toward the end of 1917, I published an article in the *Revue Neurologique*[2] calling attention again to these little understood cases, but nevertheless they continued to escape observation in France until the communication by Netter, in March, 1918, on lethargic encephalitis. I have never ceased to regard this title as inexact, for I have shown by the foreign literature and my personal records that the symptomatic tripod noted by M. Netter, namely, lethargy, fever, and ocular paralysis, was not in evidence in all these cases. I had always held that lethargic encephalitis was only a special form of diffuse encephalomyelitis such as I had described in April, 1917[2]. This conception, which was adopted in Bordeaux,[3] was promptly confirmed by numerous communications on lethargic encephalitis published in France since the end of 1919,[4] at Lyon, Montpellier, Nancy, Angers, and especially Paris. MM. Chauffard, Pierre Marie, Achard, Widal, Sicard, and others were in close accord with my point of view on all the clinical anatomico-physiological and nosological facts.

As to the detail of certain clinical forms, such as the myoclonic form or type of the electric chorea of Dubini, the theories advanced, especially by M. Sicard, repeat and reenforce in a very remarkable degree my personal views expressed long before. In 1907, I had insistd upon the rhythmic character of Dubini's chorea and the distinctive difference between these movements and those of chorea, classifying them under the name of "rhythmia," which is preferable to the more vague term myoclonia.

These acute "rhythmias," as we indicated from the beginning, are always symptomatic of grave cerebrospinal troubles, especially tuberculous meningitis and central complications due to typhoid fever, alcoholism, syphilis, measles, bronchopneumonia, etc. One of their essential characteristics is sleep or coma, contrary to what is found in tic or true chorea. The prognosis in these cases is more commonly fatal.[5] These various peculiarities are found in rhythmic encephalitis or actual myoclonia, of which numerous cases have been described in Bordeaux, Lyon, Paris, and elsewhere.

In conclusion the facts above noted established the following:

1. The form of encephalitis characterized as lethargic in May, 1917, at Vienna, and in March, 1918, at Paris, was described by me on April 27, 1917, as one of the forms of subacute or diffuse encephalomyelitis.

2. The Bordeaux conception of lethargic encephalitis or rather epidemic encephalomyelitis (or Cruchet's disease, as it is still called in the Gironde region), is in fact that which has been adopted in England, the United States, Spain, and the South American countries; accepted first in France in the great local centers such as Lyon, Nancy, and Bordeaux, it has finally been accepted also in Paris.

EPIDEMIC ENCEPHALITIS.

By E. D. FRIEDMAN, M.D.,

NEW YORK.

INSTRUCTOR IN NEUROPATHOLOGY UNIVERSITY AND BELLEVUE HOSPITAL MEDICAL COLLEGE, ADJUNCT NEUROLOGIST BELLEVUE AND MT. SINAI HOSPITALS.

CROOKSHANK speaks of this disease as being 450 years old. In 1695 Albrecht of Hildesheim spoke of lethargic fever and strabismus. A disease similar to epidemic encephalitis was described by Camerarius in 1712, following an epidemic of grippe. The disease was seen in Germany in 1745, in Lyons in 1800, in Milan in 1802, and Southwestern Europe (upper Italy and Hungary) in 1889-90; in the United States and other countries in 1895. It was noted that it followed the pandemic of influenza (1889-92) and was termed "nona." Mauthner, who had an opportunity of studying the pathology of this disease, called it acute hemorrhagic polioencephalitis. In April, 1917, Economo described a clinical syndrome which he termed lethargic encephalitis. It apparently antedated the recent pandemic of influenza. Brunell, an Australian observer, described a similar syndrome in the fall of 1917. Early in 1918 Netter described

cases in France. A number of English observers, among them Harris, Hall, and Wilson, reported instances of this disease. It was at first thought to be botulism, in view of the food conditions during the war. It was later thought to be poliomyelitis on account of the similarity in the pathological process of the two diseases. In 1918 the disease was made reportable in England; a commission was appointed to study this clinical entity. It published its conclusions in a "Report of an Enquiry into an Obscure Disease; Encephalitis Lethargica." In America the disease made its appearance early in 1918, but did not reach epidemic proportions until toward the end of the year. In February, 1919, the New York Neurological Society proposed that it be made a reportable disease. Reports were made in this country by Sachs, Kennedy, Bassoe, Neal, Abrahamson, and many others.

Pathology.—The pathology of this disease consists essentially of microscopic lesions, although there may be evident, in the gross, hyperemia of the meninges and pial edema. Very frequently minute hemorrhagic areas are seen and occasionally larger infiltrations are noted. Microscopically, we find perivascular infiltration of cells, including lymphocytes and plasma cells, but no polynuclear cells. There is also a diffuse invasion of the nervous tissues by round cells. Bassoe and Hassin found plasma cells in the ganglion cells of the subthalamic region. This cuffing of the vessels is similar to that seen in poliomyelitis, in rabies, and other low grade infections of the nervous system. It is apparently a response to a virus which is not sufficiently virulent to produce a polynuclear reaction. The lesions rarely lead to actual necrosis, but seem to interfere by vascular compression with the nutrition of the areas affected. The disease process may invade any part of the nervous system, but the favorite sites seem to be the basal ganglia and the central gray matter surrounding the aqueduct of Sylvius. This special localization explains the clinical pictures encountered in this disease. The cord changes are slight. In the cortex the ganglion cells show degeneration and are either surrounded by phagocytic glia cells or invaded by them (neuronophagia). There is usually some proliferation of glia cells. The virus probably reaches the nervous system from the nasopharynx. This has been demonstrated by Strauss and Loewe.

Symptomatology.—From what has been said one can readily see that epidemic encephalitis may give rise to various clinical syndromes. Marie, in 1890, spoke of these cases as acute multiple sclerosis. As a matter of fact, the disease is protean in its manifestations, but the vast majority of the cases show the evidences of mid-brain involvement. The incubation period is variously given as 10 to 21 days, and the prodromal period may last from a few hours to three weeks. The most striking symptoms are lethargy*, asthenia, muscular rigidity, and mask-like facies. These are present in most of the cases seen. The mode of onset is usually insidious, although some cases show an apoplectiform invasion. There usually are malaise, fever, which rarely reaches a high level, and weakness. The patients usually also show headache, some occipitocervical pain, slight rigidity of the neck, and in over 60 per cent. of the cases give a history of diplopia. In the cases with meningeal involvement there may be a suggestive Kernig sign. This, however, is not very common.

Of the cranial nerves, the one most commonly affected is the third. The internal branches are more often involved than those supplying the extrinsic ocular muscles. The pupils respond sluggishly to light and accommodation. There may be paralysis of accommodation. The other ocular nerves are also affected but much less frequently. Their involvement gives rise to ptosis, strabismus, and failure of convergence. The diplopia is easily accounted for by these ocular palsies. There is frequently a mild nystagmus in all directions. The lateral movements of the eyes are frequently carried out in "cog-wheel" fashion. There is often marked limitation in the upward movement of the eyes. This is due to lesion of the cephalad portion of the posterior longitudinal bundle. The optic discs rarely show definite pathological changes, although we have seen occasional papilloedema and even hemorrhages. A number of these cases have begun with trigeminal neuralgia from involvement of the fifth. Many of the cases showed facial paralysis of the lower motor neuron type. The incidence of seventh nerve palsy was only second to that of the third. The facial paralysis was frequently double. In most of the cases it was more evident on emotional innervation, suggesting the thalamic origin of this disturbance. Involvement of the labyrinthine division of the eighth with vertigo has also been noted. Inability to fully protrude the tongue, disturbance in the motor innervation of the palate, difficulty in swallowing, salivary drooling, impairment of chewing, and dysarthria, all suggestive of that type of pseudobulbar paralysis seen in basal ganglia disease were frequently noted. A phenomenon similar to the "fress-reflex" of Oppenheim has been noted by me in a number of the cases. These patients ate voraciously and showed a more or less definite tremor of the lower jaw. In one patient there was a persistent tachycardia out of all proportion to the rest of the findings. This patient also showed glycosuria which had not been present previously. There was some irregularity in breathing. All of these signs pointed to probable involvement of the medulla (fourth ventricle).

Many of the cases showed choreiform movements. There was a certain amount of general muscular rigidity together with the so-called "cog-wheel" phenomenon, in the execution of muscle movement. This rigidity is probably due to irritation of the tonus-controlling extra-pyramidal motor mechanism, and gives these patients the attitude of paralysis agitans. Pain usually occurred early and was associated with a certain amount of general hyperasthesia. In some of the cases the pain was radicular in type (due to posterior root involvement) and was accompanied by myoclonic movements. Hiccough was a symptom frequently noted. Abdominal tics were also commonly observed. In some cases convulsions occurred, but these were rare.

The deep reflexes were rarely altered. The ab-

*In encephalitis, lesions exist in the floor of the third ventricle. Trömner has postulated a sleep center in this area. Chronic alcoholics with persistent coma have shown lesions in this region.

dominal wall reflexes in our cases seemed depressed except in those associated with radicular pain. Here they seemed overactive. It is interesting to note in this connection that the abdominal wall reflexes are phylogenetically a late acquisition; they are first seen in primates and are not present in the newborn infant. It seems that their reflex arc is particularly vulnerable. Of the pathologic reflexes, Babinski was observed fairly frequently but rapidly disappeared. Definite pyramidal tract phenomena were not common. Many of the cases, particularly those showing the Parkinsonian syndrome, showed profuse perspiration and a subjective sense of heat.

The mental state of the cases varied from active mania to severe depression. Delirium was common. One of our cases showed a definite jocoseness (witzelsucht) so commonly seen in frontal lobe lesions. Many of the cases showed mild confusion. A certain amount of euphoria existed in most of the cases seen, but in our judgment this was not a true euphoria. The patients simply showed emotional indifference. This can easily be explained on the basis of the favorite localization of the pathologic process in the basal ganglia. We know that the optic thalamus is the center of our affective life; it is the seat of our perception of pain and pleasure in the sense described by Head. Disease of this region produces, therefore, a loss of emotional tone. The expressionless facies, the thalamic type of facial paralysis, the occasional occurrence of hemianopsia, and central (thalamic) pains, all seem to point toward disease in this area.

The occurrence of choreiform and athetoid movements, some of which persisted long after convalescence was definitely established, also indicates the selective affinity of the virus for the basal ganglia. The cases showing katatonia resemble very much some types of dementia præcox. The general muscular rigidity, which is very much like that seen in pseudosclerosis (Strumpell-Westphal) has been ascribed to lesion of the corpus striatum, the choreo-athetosis to lesion of the thalamic or subthalamic region. The ataxia is said to be due to lesion of the brachium conjunctivum. Marburg divides the brachium conjunctivum fibres into three groups: tegmentocerebellar, lesion of which produces athetosis, thalamic fibres, injury to which causes chorea, and cortical fibres which are concerned in the production of tremor. He also ascribes ataxia to a lesion of the tegmentum between the substantia nigra and the oculomotor nucleus. Strumpell has recently linked up pseudosclerosis, progressive lenticular degeneration, dystonia, musculorum deformans, paralysis agitans, and the syndrome du corps strié (C. Vogt). He groups all of these under the term "amyostatic symptom complex" and ascribes them to changes in the corpus striatum, thalamus, subthalamic region, pons and dentate nucleus.

Retention of urine early in the disease was very frequently observed. This bladder symptom is due to involvement of its center in the basal ganglia. Experimentally, irritation of the midbrain leads to dilatation of the pupils, sweating and contraction of the bladder.

The spinal fluid findings, as a rule, were meagre. In some of the cases there were no abnormal findings. In others there was a slight increase in the globulin and a moderate increase in the number of cells, most of which were lymphocytes. In these cases the spinal fluid tension was usually slightly increased and the puncture often gave some relief.

Prognosis.—The mortality rate varied with different observers, and is given as ranging between 15 and 50 per cent. Altered mental states, cranial nerve palsies, may remain as sequelæ. I have noted a number of instances of stubborn and persistent headache. The paralysis is rarely permanent because the lesions are not, as a rule, destructive in type. The Parkinsonian cases usually are longest in duration and are most apt to remain permanently impaired. So, too, the cases with choreiform movements seem to be less likely to recover from their ailment. The fixity of the pupils may remain more or less permanently, and we may have to revise our notion on the significance of a fixed pupil. It is still premature, however, to make dogmatic statements with reference to the final outcome of these cases. There is a tendency in some cases to chronicity with periodic exacerbation of symptoms.

Bacteriology.—The bacteriology of this disease was studied by Wiesner, who produced the disease in monkeys, the brains of which showed the characteristic pathological changes and from which he recovered a pleomorphic coccus. He found that his streptococcus pleomorphus, besides causing encephalitis, produces a peculiar hemorrhagic diathesis. This may account for the apoplectiform onset in some cases. Landsteiner demonstrated the same organism in cases of polymyositis. Cleland and Campbell succeeded in giving the disease to the horse, calf and sheep. Wilson recovered an organism from the cases of acute infective polyneuritis (a form of encephalitis), which Bradford described. He also gave the disease to monkeys. Sabatini recovered a Gram positive diplococcus from these cases.. Strauss and Loewe have recovered an organism from the brains of these cases. They have been able to reproduce the disease in monkeys and rabbits, and have passed the organism through more than sixteen generations. Levaditi has confirmed their work. All observers are agreed that the virus belongs in the group of filtrable organisms, and is similar to the globoid bodies described by Flexner and Noguchi in poliomyelitis.

Relation to Poliomyelitis.—The relationship between this disease and poliomyelitis is very close pathologically. The virus in both cases apparently reaches the brain from the nose and throat. Yet the localization is different, poliomyelitis attacking chiefly the cord, while encephalitis seems to favor the midbrain. The seasonal incidence is different, poliomyelitis usually occurring in the spring and summer, while encephalitis seems to run parallel with influenza during the fall and winter. The paralyses, too, are more or less permanent in poliomyelitis and more transitory in encephalitis. MacNalty, of the British Commission, speaks of the relationship between poliomyelitis and encephalitis as being similar to that between typhoid and paratyphoid.

Diagnosis.—This disease must be differentiated from tuberculous meningitis. The absence of clin-

ical evidence of tuberculosis elsewhere, the absence of the tubercle bacilli containing pellicle in the spinal fluid, the animal inoculation test and the subsequent course should help to eliminate it. Tuberculous meningitis, too, usually occurs in the first years of life and is rare after the age of ten. In encephalitis 40 per cent. of the cases occur in those over ten years of age. The meningitic signs also are more marked in tuberculous meningitis. The serology serves to differentiate it from cerebrospinal lues.* Early in the course of the disease typhoid and influenza would have to be ruled out. The clinical manifestations are so manifold that almost every neurologic syndrome can be produced. We have seen one patient in whom the diagnosis of progressive muscular atrophy was made. This was due to the marked spinal involvement in this case. Another of our cases showed the clinical evidences of involvement of the pulvinar (hemianesthesia-hemianopsia).

Treatment.—This is wholly expectant and symptomatic. Spinal puncture helps in some instances.

CLINICAL LOCALIZATION OF THE VERMIFORM APPENDIX.

BY ALBERT ABRAMS, A.M., M.D., LL.D.,

SAN FRANCISCO, CAL.

LOCALIZATION of this process has been described elsewhere[1] under the head of "Abrams' Electronic Reactions." The following simplified method is easier of application.

Exactions.—The subject must stand facing the geographical west, preferably grounded on a metal plate connected by wire[2] to a faucet or radiator. A wire attached to subject's leg and connected with radiator or faucet suffices.

Method.—Pass either pole of a bar magnet slowly over the right inguinal region and then percuss. An area of dullness in the norm can be elicited, as a rule, midway between a line drawn from the right anterior superior iliac spine to the navel. This area of dullness corresponds to the appendix. This method of localization has been repeatedly confirmed by the *x*-rays.

Note that the dullness may persist for hours; that it descends during forcible inspiration and ascends during expiration, provided there are no adhesions.

Note that the dullness is dissipated at once if the patient swerves to the magnetic meridian, and that dullness returns when the posture facing west is resumed.

If the positive pole of a magnet were used, the negative pole of the same magnet presented to the area of dullness would dissipate it and *vice versa.* If a horseshoe magnet (neutral radioactive energy) were used, the dullness would be dissipated by grounding the dull area with an electrode leading to a ground plate, radiator, or faucet. If the physician facing west presents his grouped finger tips (right hand) to the right inguinal region after the manner suggested in using the magnet, the positive energy of his finger tips will elicit an area of percussional dullness which can be dissipated by the finger tips of his left hand (negative energy).

If the subject separates his feet and arms from the body during percussion, dullness is accentuated.

The foregoing data are easy of confirmation. They show that the appendix is essentially a "tissue condenser" to store energy and may be employed for that purpose in constipation.

The writer has already shown[3] how the appendix may be emptied and how this fact may be ultilized in appendicitis. It remains to be observed how a diseased appendix may respond to the methods suggested by the writer.

2135 SACRAMENTO STREET.

*It may be that the cases of exhaustion pseudoparesis recently described by J. Ramsay Hunt were early instances of the subsequent epidemic of encephalitis.

French Children and the War.—In a recent report submitted by the American Red Cross Headquarters at Lille, France, based on figures furnished by the Municipal Bureau of Hygiene, the effects of the war on French children are given. The prewar population of Lille was 200,000. The birth rate has shrunk from nearly 4,900 in 1913 to only 600 in 1918, the actual figures indicating a total loss of 15,000 births during the war. The death rates according to ages are not known, but since the armistice a survey has been made in all public and private schools with a view to obtaining appropriate food for all children whose development has been retarded and to place all those who show signs of tuberculosis in the care of institutions and welfare organizations. Of 18,000 children in school at Lille at the time of the armistice, over 6,000 had to be sent to hospitals or convalescent centers. This survey indicated that 60 per cent. of the school population showed signs of arrested development, while about 40 per cent. gave evidence of ganglionary or pulmonary tuberculosis. In one typical school, out of two hundred and ten examined, only one was in normal health.

CANCER OF THE ILEOCECAL VALVE.

MALIGNANT disease of the ileocecal valve is one of the most uncommon growths of the intestinal tract. Its frequency is difficult to state statistically because up to date it has been studied either with cancer of the terminal portion of the ileum or as a particular type of cancer of the cecum, which, according to Desmaret, is the starting point in 66 per cent. of the cases. Quite independently of cancers of the valve which are merely extensions of cecal neoplasms, and those of the terminal portion of the ileum, there is a cancer of the valve strictly speaking. It frequently invades the cecum and respects the ileum, causing little, if any, stenosis there; this is the typical ileocecal valve cancer. There is, however, yet another form which appears to be about as frequent, namely, the growth which arises on the ileal aspect of the valve, in no way involving the cecum, invading the last portion of the small intestine, and resulting in a very tight stenosis.

The cecovalvular and ileovalvular forms offer themselves for study in two different aspects: a laterally situated tumor implanted on a rather broad base, on one of the lips of the valve and spreading out in the cecum or ileum; an annular growth—ring cancer—much more common, which involves both lips of the valve, and assumes the aspect of a thick cuff closing down the valvular opening. This cuff invades the proximal side of the ileum, transformed into a narrow canal ending sharply in a point. On the cecal aspect, extension takes place on a much larger scale, reaching the ascending colon or even going beyond. Involvement of the regional lymph-nodes is not common, at least it is late in occurrence, the neoplastic invasion involving only the lymph-nodes in near relation to the lesion, those situated further away presenting only inflammatory changes. The mesentery is often involved; visceral metatases, which are infrequent, are encountered along the digestive tract, in the liver, lung, and ovary.

Malignant growths of the ileocecal valve give rise to two sets of accidents: (*a*) to early phenomena of incomplete intestinal occlusion and chronic occlusion, which manifest themselves by characteristic symptoms, such as pain, variable gastrointestinal disturbances, one of the most frequent being periods of constipation followed by copious diarrhea. (*b*) Later on these early disturbances become systematized. The dilatation and hypertrophy of the muscular layer of the ileum and mucous hypersecretion give rise to Ricard-Mathieu's syndrome, namely, clapotage and declivous pseudo-ascitic dullness. The symptomatology is completed by intestinal evacuations and the presence of a tumor in the right iliac fossa. The evolution of this showy progressive form of occlusion ends either in acute intestinal occlusion, which may be the first symptom of the process, or in a series of temporary attacks of acute occlusion and finally in cachexia. Or, on the other hand, cancer of the ileocecal valve may produce accidents of chronic invagination of the ileocecal segment into the large intestine. This is special to growths of the valve, cecal growths rarely giving rise to it. The neoplasm of the valve remains mobile for a long time without adhesions to the surrounding viscera. Two principal symptoms characterize invagination of the valve: a tumor and passage of a bloody mucous discharge. The invagination can never be reduced and will require resection of the portion invaginated. Briefly, the rapidity of the accidents of stenosis and chronic intestinal occlusion and frequency of invagination are the essential characteristics of this lesion.

Treatment of ileocecal cancer is, of course, surgical, and is one of the best examples of the utility of medicosurgical collaboration. The physician will be consulted for the painful phenomena and gastrointestinal disturbances, and it rests upon him to make an early diagnosis which is the prelude to a successful surgical interference.

THE ETIOLOGY AND PATHOGENESIS OF OSTEOMATA OF THE ORBIT.

FROM the viewpoints of both etiology and pathogenesis the origin of orbital osteomata is most obscure. Sichel and Mackenzie were of the opinion that these growths resulted, in some cases, from trauma, but that syphilis and scrofula played the most important part in their production. According to Chauvel, scrofula does not appear to have much if any importance in the etiology as he never met with any instances of this morbid process where it could be invoked. Wecker maintained that if exception were made of the rare instances of syphilitic exostosis, the only etiological factor was the arthritic or rheumatic diathesis, and still this was in contradiction with the ages of the patients presenting osteomata of the orbit. Out of a total of forty-nine cases Berlin found only two in which there was a syphilitic history, one of them being cured by antiluetic treatment. Berlin believes that traumatism may play a part in but few instances, and explains this infrequency by the fact that the orbital walls are protected against external violence. Tchilinghiroff found a history of traumatism in eleven cases out of a total of sixty, or 18 per

cent., and states that this factor so frequently invoked can only be regarded as probable in osteomata of the margin of the orbit as in all the eleven cases this was the site of the bony growth.

Modern views regarding scrofula, syphilis, and the arthtritic diathesis in the etiology of many affections have been, rightly or wrongly, rather against them in many instances, but in the case of osteoma of the orbit it is probably correct to say that these factors have little or no part whatsoever in the causation of this neoplasm. These growths may, perhaps, be related to some disturbance of evolution at the time the walls of the orbit and those of the sinuses are forming. The fact that they grow very slowly and that their onset takes place in early life lends support to this view. It is, in fact, surprising to note that the majority of bony tumors are manifest in very young subjects and have existed from early life. Of seventeen cases of orbital osteoma in which the patient's age was given, Chauvel found eight who were between ten and twenty years old, two between twenty and thirty, five between thirty and fifty, and two over fifty. Tchilinghiroff's results are likewise striking in this respect. Of fifty cases in which the age is given thirty-two subjects were from fifteen to twenty-five, eight from twenty-five to thirty-five, and ten were over thirty-five years old. On account of the very slow evolution of the growth too great an exactitude cannot be attributed to these figures, but it nevertheless is apparent that the greater number of cases begin during the period of growth, or between ten and twenty-five years of age. There is, consequently, in this respect an analogy between these morbid productions and osteomata of the epiphyses in adolescence, and Duplay was of the opinion that osteomata of the orbit were growths resulting from the nutritive activity of early life. It is also known that the orbit is the region which offers the most variations in its embryonal evolution. On the one hand, the frontal and maxillary sinuses continue their development up to an advanced age; on the other, the connection existing between the different bones, particularly the frontal, superior maxillary, ethmoid, etc., is so close that reciprocal disturbances may occur during their development.

THE FAILURE OF A MISSION.

THE newspapers report that Dr. Serge Voronoff of Paris, who figured somewhat conspicuously in the cables last autumn as the discoverer of the rejuvenating virtues of the "interstitial glands," has recently arrived in New York. His method differs from that of Brown-Séquard in that he follows Lydston's operation of engrafting a section of the gland itself instead of injecting a testicular extract. According to the *Tribune* of July 19, Dr. Voronoff, the day after his arrival in this country, announced that his purpose in visiting America was to carry his operation a step farther by using the human testicle instead of that of an ape or other animals. the French law forbidding such an operation. He was confident, he said, that he could graft the "interstitial gland" of a man to whom death had come while he was in perfect health into the body of an old man with most beneficial results to the latter, providing he was in a position to obtain the gland immediately after death. The victim of an accident or of the electric chair at Sing Sing would yield a suitable gland, he said.

This is awfully discouraging. We had hoped that one of the minor blessings flowing from the great tragedy of the war would be the freedom of our devoted country from further exploitation by foreign inventors and discoverers of medical wonders —the turtle serum vendors and the twilight sleepers. But now with Germany down and out, up pops France. It was hoped and expected that she would take the place which belongs to her as the leading exponent of Continental medicine, but this is a sorry beginning. There has been a good deal of indignant criticism of Dr. Voronoff's presumption in coming to America to advertise as his own a procedure which was introduced as long ago as 1914 by Dr. Lydston of Chicago and has been practised in this country since then many times and by many surgeons. It does not seem credible, however, that any man would knowingly carry such a load of coals to Newcastle, and we are inclined to believe that it never occurred to him that anyone in the wilds of America could have previously evolved such a brilliant idea. His journey will not have been in vain, however, if its outcome serves to warn others against such foolish enterprises.

ACTION OF THE *X*-RAYS ON THE SUPRARENAL GLANDS.

THE *x*-rays behave toward the suprarenal glands in the same fashion as they do in the case of other glands of the organism when given in sufficient doses—they diminish the functions. When given in cases of hypertension, the *x*-rays will diminish the blood-pressure, as the clinical experiments of Cottenot (Thèse de Paris, 1913) have amply proved. This fact brings up another argument in favor of the theory which considers hypernephria as a factor of hypertension, because a rational therapeutic measure is brought to bear on the very cause of this functional disturbance, and at the same time that the pressure drops, the symptoms due to hypertension improve. The value and duration of the lowering of the blood-pressure, as well as the functional changes, are variable according to the subject. In some patients the improvement has been maintained for months, in others it has been necessary to renew the *x*-ray applications from time to time. It is in the purely hypertensive cases without appreciable renal lesions that the best results have been obtained, and subjects with mild arteriosclerosis without albuminuria have also been benefited. In albuminuria with high blood-pressure, the latter has been decreased, but no functional improvement naturally takes place. In cases of albuminuria with arteriosclerosis the treatment has been found of no avail, although the amount of

albumin is not increased by the treatment. By massive repeated radiations, Cottenot has been able to produce lesions of the suprarenals in dogs. The lesions were found in both the medullary portion and the cortex of the kidney, the latter being less involved. The lesions consisted of destruction of the cells by cytolysis and chromatolysis. In one animal a transformation *in situ* of the glomerular cells was found which in their shape, cytoplasm, nucleus, etc., had become identical with the normal cells of the fascicular portion. This can be interpreted in two ways: either the *x*-rays hastened the normal evolution of the cells of the glomerulæ or the process was a supplementary one destined to replace the destroyed cells. All these lesions have been found in dogs autopsied from eight to forty days after beginning the *x*-ray radiations. The suprarenals of animals who had been *x*-rayed for months were found absolutely intact, so that if in these cases if there were glandular lesions they must have been transient and the prolonged action of the rays did not prevent the regeneration of the gland. In only one dog was there any marked lowering of the systolic and diastolic blood pressures, and this was one of the animals whose suprarenals showed on post-mortem examination important destructive lesions.

Pseudo-Pregnancy in a Subject with Major Hysteria.

Infroit and Royole relate a case published in the *Bulletin et mémoires de la Société anatomique de Paris* for January, 1920, xvii, 1, of a woman aged 40, very subject to crises of major hysteria, both convulsive and vertiginous. She had never been pregnant but was fond of the pretence that she had had a romantic love affair and had become pregnant. She presented the abdominal enlargement and gait of advanced pregnancy and there was no sign of menstruation in the hospital in which she had for some months been interned. Upon special examination she gave the appearance of a woman 7 or 8 months pregnant and there was marked tympanitic resonance in the left hypochondriac region, as if the intestines were crowded into that area. The gynecological examination revealed that the internal genitals were quite intact. The abdomen showed marked resistance to palpation but upon diverting the attention it became supple for the moment, once more to simulate a gravid abdomen. To exclude air-swallowing, the only condition which could come and go in this fashion, the radioscope was used and it was found that the patient was an aerophage. This behavior seemed to be voluntary and deliberate, the woman swallowing air forcibly until she had produced the distention. The diaphragm did not participate in the mechanism. The gas presumably escaped through the anus, but this does not seem to have been proved outright. Purgatives evidently prevented the simulation on account of the increased pressure in the intestine, while after administration of paregoric and bismuth simulation seemed to be facilitated. The diagnosis in brief was simulation of pregnancy by voluntary air swallowing without participation of the diaphragm by a woman of notorious hysterical makeup and behavior.

Plurality of the Organisms of Syphilis.

Pagniez contributes an article on the recently published finds of Levaditi and Marie in *La Presse Médicale* for May 1, 1920, xxviii, 27. Despite the plausibility of their position on the dualism of virus the question has not been completely settled. It has been proved that when the virus of a paretic brain has been passed through the rabbit a syphilis is developed which differs from banal syphilis. But this cannot be shown to mean that the original syphilis in the paretic was of a special form, for the organism may have undergone a mutation in the diseased brain. It has yet to be shown that the same change does not occur in an ordinary tertiary lesion. In other words, we have not yet been shown that this difference in virus means that there is a special neurotropic form. But these questions may be attacked in the laboratory, so that speculation is out of place. The possibility of special strain should also be studied in connection with other metasyphilitic affections, for clinically the latter, of which there are a number not associated with nervous lesions, are distinct from ordinary gummatous syphilis. So far as the general trend of microparasitology is concerned multiplicity in specific germ life is shown by the increasing use of polyvalent serums in practice. This idea is inseparable from that of manifold strains of all pathogenic germs. We see this tendency in regard to the tubercle bacillus, the pneumococcus, the streptococcus, etc. A priori there is no reason to predict that the treponema will be an exception in this respect. The belief in a neurotropic strain of the spirochete should not have too much cold water poured on it, for it gives some hope that a remedy for paresis and tabes may some time be devised.

News of the Week.

International Conference on Tuberculosis.—Announcement has been made by the National Tuberculosis Association that an international conference on tuberculosis will be held in Paris during the week of October 7. This will be the first similar gathering since the one held in Rome in 1912.

Good Advice to Germans.—Professor Franz Boas, head of the department of anthropology at Columbia University, New York City, is reported to have received so many letters from German colleagues and students asking his assistance in securing for them desirable appointments in the United States, that he has written an open letter to Dr. Felix von Luschan, professor of anthropology at the University of Berlin, to be published in leading German papers. The substance of the letter is the advice to all Germans to stay at home, and to devote the time they formerly spent in the army to the farm and the factory.

Bubonic Plague in the City of Mexico.—The Mexican Federal Board has announced that a recent death in Mexico City was caused by bubonic plague.

Drug Regulations Assailed.—The Federal Grand Jury, in connection with certain indictments for violation of the Harrison Drug Act, made the recommendation that the same regulations be adopted for drug control as those which control the sale of

liquor. In other words, that the party to whom a license is issued shall be required to give a bond and then sell only on certificates issued after due investigation by the Collector of Internal Revenue, or upon physician's prescriptions.

Movement to Restore the "Personal Equilibrium" of Disabled Soldiers.—The New York Rotary Club has started a nation-wide movement to interest business men in the work of restoring "the personal equilibrium" of disabled veterans of the World War and of fitting them for future usefulness.

Red Cross Supplies to China.—According to advices from Shanghai, more than a thousand tons of American Red Cross Supplies, of an estimated value of more than $500,000, originally shipped to Siberia, have been transshipped to Shanghai and are to be distributed to mission hospitals of all denominations throughout China.

Radium for Cancer Research.—The State of New York has bought two and one-quarter grams of radium for the Institute for Malignant Diseases at Buffalo. The radium has been undergoing a scientific test by the Bureau of Standards at Washington, D. C. One gram of the radium, valued at $120,000, was delivered by the Bureau of Standards on July 27 to Arthur Roeder of New York City, representing the State of New York. This gram is said to represent 125 tons of ore.

Resignation of the Counsel of the State Society.—Mr. James Taylor Lewis, counsel for the past two decades of the Medical Society of the State of New York, has resigned, the reason given being that the society declined to raise his salary. It is said that a resolution offered in the House of Delegates at the recent annual meeting, condemning Mr. Lewis for agreeing to defend a member of the society charged with an alleged violation of the Harrison law, may have had something to do with his present action. The resolution was defeated, but the animus which prompted its introduction was evident.

Tuberculous Soldiers Like Saranac.—When the order from the New York office of the United States Public Health Service directing the transfer of soldiers under treatment at the Home Sanatorium, Saranac Lake, to service sanatoria in other parts of the country, was received a strike was called. Of the 210 ex-service men undergoing treatment for tuberculosis contracted while in service, 200 voted to disregard the order. The American Legion of New York State recommended that the men be permitted to remain at Saranac Lake.

Aid for Mentally Afflicted.—At a special executive meeting of the Home and Farm Institution for Mental Convalescents held in New York City recently plans were made for a drive for a membership of 50,000. Simultaneously with this membership drive will be conducted an intensive campaign to raise $1,000,000 for the purpose of constructing a large institution in the Catskill Mountains, where the poor who are nearing or have reached the border line of insanity will be treated in an effort to restore them to mental vigor.

War Risk Cases in Naval Hospitals.—Sixteen naval hospitals have been notified that they will be expected to take war risk cases for reconstructions, provided there is available personnel. These patients are to be in addition to Navy and Marine Corps cases. There are now 3,200 beds in naval hospitals, according to the *Army and Navy Journal*, available in temporary buildings erected during the war, but at the Bureau of Medicine and Surgery it is stated that there is no personnel to look after these hospitals.

Radium Clinic.—The Nathan and Miriam Barnert Memorial Hospital Association of Paterson, N. J., has opened a radium clinic under the charge of Dr. William Spickers. The institution has acquired fifty-five milligrams of radium and is prepared to treat patients referred from other hospitals as well as those who come directly to this hospital.

Dr. Jacob Geiger has been appointed director of the pathological laboratories of the New York Diagnostic clinics. After an extensive survey of the better American laboratory systems he will reorganize the laboratories of this institution.

Dr. Sarah J. McNutt has removed her office from 265 Lexington Avenue to the Park Avenue Hotel, New York City.

Police Plan Sanatorium.—A sanatorium in the Catskills or the Adirondacks is to be erected for members of the New York Police Department with the funds collected from the annual police games to be held August 21 and 28 at the Gravesend track.

Dr. Blanche Norton of Eldon, Iowa, has had conferred upon her by King Alexander of Greece the Order of King George I. Dr. Norton, who is said to be the first woman to receive this order, as a member of the American Committee for Relief in the Near East, distinguished herself at Kerrassunde, Anatolia, by treating Greek orphans for trachoma, contracting the disease herself.

Dentist Teetotaller Dies at One Hundred and Three.—Dr. Jesse C. Green of West Chester, Pa., died July 26, as the result of falling from a step ladder while hanging a picture. He was born in 1817. He never used tobacco or intoxicants, and took his last cup of coffee in 1844. Until six years ago he is said to have been in the habit of taking a daily ten-mile bicycle ride before breakfast. For a number of years Dr. Green was president of the Pennsylvania Dental Society, for nearly fifty years he was a local volunteer weather bureau agent, and for more than seventy years he was treasurer of a local fire company. He was a member of the Society of Friends.

Dr. Magruder's Body Arrives.—The funeral of Dr. Ernest Pendleton Magruder, a chief surgeon of the American Red Cross, who died during the epidemic of typhus fever in Belgrade, Serbia, April 8, 1915, was held in Washington, D. C., July 29. The body, which arrived at Hampton Roads aboard the United States naval ship *Patoka*, was interred in the family burying ground in Prince George's County, Maryland.

The Late Dr. James W. Markoe.—The following resolutions were adopted by the Board of Governors of the Lying-in Hospital on May 25:

Whereas, In January, 1890, due to the initiative and efforts of Doctor James W. Markoe, the work as now conducted by the Society of the Lying-In Hospital of the City of New York, had its inception at the Midwifery Dispensary, 314 Broome Street, which in August, 1892, was merged with the society, and, Whereas, From 1892 till 1902 the work of the

Society was carried on at 314 Broome Street and in the reconstructed Hamilton Fish Mansion on the site of the present hospital, and, *Whereas*, In January, 1902, due to the inspiration of Doctor James W. Markoe and the generosity of the late J. Pierpont Morgan, the Society of the Lying-In Hospital of the City of New York began its work in the building on Second Avenue between Seventeenth and Eighteenth streets, which it now occupies, and, *Whereas*, From 1890 until March, 1918, when he retired, Doctor Markoe gave of his best to the organization, medical and surgical work of the hospital, giving aid and comfort to thousands of poor women and children and with his coworkers bringing to a full realization the hopes for the institution which he had entertained for so many years, and, *Whereas*, By his untimely death the City of New York has lost an honored and helpful citizen and the poor of the city a skillful surgeon and sincere friend, therefore, be it *Resolved*, by the Board of Governors of the Society, in meeting assembled that they hereby express their profound sorrow at the untimely death of Doctor Markoe, and hereby extend their deepest sympathy to his family in their bereavement, and be it further *Resolved*, that these resolutions be spread upon the records of the Society printed in the Annual Report for the current year and that a copy of the same be engrossed and sent to Mrs. Markoe.

(Signed) LEWIS CASS LEDYARD,
President.

(Signed) JAMES GORE KING,
Secretary.

Obituary Notes.—DR. JOHN IRVING VAN WERT of Patton, Pa., died July 25 at the Park Avenue Hotel, New York City, after a short illness. He was fifty-five years of age, and was graduated from Bellevue Hospital Medical College in 1887. He was a member of the Pennsylvania State Medical Society and of the American Medical Association.

DR. HARRY E. CAMPBELL, formerly a practising physician of Pittsburgh, Pa., died in New York City July 25 from cerebral hemorrhage, at the age of sixty-one. He was graduated from Jefferson Medical College in 1881, served as interne at the Philadelphia General Hospital, and practised for twenty-five years in Pittsburgh, devoting his attention chiefly to surgery. Three years ago he gave up his practice, presumably because of financial reverses, came to New York, and, as was revealed after his death, had since been employed as dishwasher in a local restaurant.

DR. EVA HARDING of Topeka, Kansas, died of cardiac disease July 27, at the age of sixty-three. She was graduated from Hahnemann Medical College and Hospital of Chicago in 1882 and had practised in Topeka since 1892. Dr. Harding was candidate for the United States Senate on the Socialist ticket at the general election two years ago, and for the office on that party's present primary ticket. Four years ago she was Democratic nominee for Congress.

DR. LAURA A. C. HUGHES of Boston, Mass., who was known as the "Angel of Montauk" for her work as a nurse among troops at Camp Wyckoff, Long Island, during the Spanish-American War, died July 30, at the age of sixty. She was graduated from Tufts Medical School in 1895, and was a member of the Massachusetts State Medical Society.

Correspondence.

OUR LONDON LETTER.

(From Our Own Correspondent.)

LONDON, July 7, 1920.

Educating the Public to Combat Disease.—An influential deputation from the Society for the Prevention of Venereal Disease waited upon the Minister of Health on July 2 and advanced suggestions for awakening the country to the dangers of the disease and the means for combating it. In urging upon the Minister of Health the acceptance of the principle of immediate self-disinfection, the introducer of the deputation, Lord Willoughby de Broke, said that first of all the society asked for the immediate self-disinfection of those who had exposed themselves to risk. Its policy was that the Ministry, as responsible for the health of the nation and for the prevention of the spread of venereal disease, should take such steps as would educate the public on the whole of this extremely important matter, and that those who insisted, after warning, in exposing themselves to risk should at least have an opportunity of being equipped by authoritative instruction with regard to the disinfectants they ought to ask for and the methods by which these ought to be applied. Dr. Addison said in reply that it was not enough to urge people to do something or other; he had to satisfy himself that it was the right thing to do and to obtain a sufficient measure of public support in doing it. What struck him was that they were dealing with a subject which did not rest on the basis of ascertained fact. With regard to self-disinfection, if the Government took the responsibility of issuing throughout the country the kind of instruction suggested by the society, they must have an overwhelming case in order to contend against the deep-rooted national opinion, which would say that the Government was encouraging vice. It was no good shutting their eyes to these facts, that any systematic effort of that kind would incur risk and that there might be a big wave of feeling in opposition. Therefore it was necessary in the first place to have an overwhelming case in order to convince the public that the particular method they proposed should be adopted, and that notwithstanding all the prejudices which might well be aroused, their case would be so strong as to be really beyond question. If they were not successful they would put back the movement a generation. Supposing owing to the failure of its application the scheme did not succeed, the result would be worse than if they had never tried it, because they would therefore prejudice other methods. Furthermore, another great objection would be raised, that to adopt this method as regards the population as a whole would be held as doing something which would tend to encourage them to run risks.

Insurance Medical Benefits Changes.—On July 3 important changes in national health insurance came into force. These affect more than fifteen million workers besides their employers. According to Sir Walter Kinnear, Controller of the National Insurance Department of the Ministry of Health, the changes are designed to bring health insurance more into line with the changed

needs and economic conditions of the country, to bring them, in fact, into closer relations to the lessened value of money and the higher cost of living. Steps are being taken to improve the medical benefit. Medical officers are about to be appointed by the Ministry of Health with the view of improving the conditions both of the diagnosis and the treatment of disease. They will cooperate with the insurance practitioners in difficult and doubtful cases. They will also give assistance in cases of doubtful incapacity and of prolonged claim to benefit. The number of patients on the panel of any one medical practitioner is to be restricted to 3,000, but it does not follow that practitioners in partnership, or with an assistant, will be allowed to take 3,000 each. A practitioner is required to provide proper and sufficient surgery and waiting room accommodation for his patients. In case of accident or sudden emergency the nearest insurance practitioner may be asked to attend, although the insured person is not actually upon his panel. A person who may wish to change his medical attendant will be able to do so at the end of any half year, instead of at the end of any year. Medical treatment may be provided for the wives and families of insured men; convalescent homes may be established for members, and increases may be given in the cash benefits under the act. The benefit societies of Great Britain have accumulated funds amounting to no less than £78,000,000. In future it is estimated that nearly £30,000,000 a year will be expended on sick benefits. At present the payments made during sickness represent a loss of working time in Great Britain and Ireland of no less than 25,000,000 working weeks a year.

Emergency Distribution to the London Hospitals.—An emergency distribution of the London hospitals of £250,000 from King Edward's Hospital Fund has been decided upon in order to relieve their pressing needs. These grants have been made with the object of assisting the hospitals to carry on their work; and it is the hope of the fund that, where the committee of management are experiencing any special difficulty in raising funds for maintenance, the grant may give them both the opportunity and the encouragement to consider methods of improving the finances, and in particular (a) to consider whether the income of the hospital can, without detriment, be increased by taking some special steps, e.g. by the organization of contributions from employers or from employed, or from patients who can afford to pay, or by other methods; (b) to take whatever steps may be necessary and practicable to keep the expenditure within the available or prospective income, e.g. by postponing bed extensions, and by exercising more stringent control over cost of working, especially where the cost is substantially in excess of the average of the hospitals in the same group in the Fund's statistical report.

Anderson Hospital for Women.—To celebrate the completion of the collection of £50,000, the sum which was asked for to endow fifty beds at the Elizabeth Garrett Anderson Hospital in Euston Road as a memorial to the founder, a pleasant ceremony took place in one of the surgical wards of the hospital on the afternoon of July 5. Sir William Plender who made the financial statement, said that in 1916 the hospital had its fiftieth anniversary and it occurred to Lady Hall that the event might be celebrated by the raising of an endowment fund of £50,000. This became the memorial fund on the death of the founder, Dr. Elizabeth Garrett Anderson. Lady Hall raised this sum under the most difficult conditions in time of war. She did not go to the general public, but to the girl and women workers, and enlisted their sympathy.

Scotland's Record Birth Rate.—The most remarkable features of the vital statistics of Scotland in the first quarter of 1920 are a high birth rate, a high marriage rate, and a low death rate. The number of births registered during the quarter was 37,748—males, 19,261; females, 18,487. This is the largest number registered in Scotland during any quarter since the institution of national registration. It is 66.1 per cent. more than the first quarter of the previous year. The birth rate was correspondingly high. It was 30.9 per 1,000, which is higher than those of all quarters since 1891 and higher than those of all quarters subsequent to the second quarter of the year 1905. Marriages registered during the quarter numbered 11,751, and the marriage rate was 9.6. Both the number and the rate exceed those of all first quarters since the institution of national registration. The deaths of the quarter numbered 18,925 and the death rate was 15.5 per 1,000. In only one previous quarter, 1918, has there been a lower death rate recorded.

New Convalescent Camp at Epsom.—A new convalescent camp has been set up at Epsom, some twenty miles from London, by the Ministry of Pensions, and organized by Colonel Bostock. Its object is to afford a disabled man a real training in some occupation suitable to his disability, while at the same time he receives the treatment he requires. On reaching the camp the disabled man has a consultation with the medical officer and the superintendent of occupations. The medical officer, after examining the man, indicates what kind of work may be done. The exact type is then arranged between the man and the superintendent of occupations. Even then, however, the matter is left open until a test has been made in actual experience. As well as the practical branches there are lectures and demonstrations. It is said that the men are eager to learn and it is felt that a serious, and it is to be hoped a successful, attempt is being made to solve a very grave problem.

The Eleventh Annual Meeting of the Oxford Ophthalmological Congress.—This congress will meet at Oxford on July 15 and 16, 1920. The proceedings will take place in the Department of Human Anatomy in the University and will consist of addresses, demonstrations, and a scientific and commercial museum. The Doyne Memorial Lecturer for the year is F. R. Cross Buslot, who will lecture on the nerve paths and centers concerned with sight. A discussion on perimetric methods will be opened by Dr. Luther C. Peter of Philadelphia, who will limit his remarks to the new methods of perimetry and the types of cases for which they are especially adapted.

Honor for Sir T. Clifford Allbutt.—It has just

been announced that with the King's approval, Sir Thomas Clifford Allbutt, Regius Professor of Physics in the University of Cambridge and president of the British Medical Association, is to be sworn a member of the Privy Council.

Archbishop of Canterbury Refuses to Confer a Medical Degree.—It is a curious fact that the Archbishop of Canterbury has the power to confer medical degrees. This right was granted when the medical profession was at a low ebb and the church was more powerful than at the present time. Needless to say that what is known as a Lambeth degree (Lambeth Palace is the old palace of the Archbishops of Canterbury situated on the south side of the Thames) is seldom conferred, and then merely as an honorary title. However, there is an extraordinary sentiment and strong movement in Great Britain to give a medical degree to Mr. Barker, a well-known bone setter, who did great work during and after the war in relieving and removing disabilities of soldiers caused by war injuries. It is felt by a certain section, and it may be said influential section of the public, that a man so skillful and with such really wonderful manipulative powers should not be regarded as a quack but should be placed on an equality with members of the medical profession. The universities and medical and surgical bodies in Great Britain that have the power to confer degrees and qualifications do not see their way to upsetting all precedent and conceding to a man who has never been trained in recognized schools of medical and surgical work, or passed examinations therein, their degree or license to practise. Accordingly, a petition signed by over 300 past and present members of Parliament in favor of a Lambeth medical degree being granted to Mr. Barker "in view of his unique and distinguished services to suffering humanity and the cause of science through a long period of opposition, contumely, and persecution" was presented to the Archbishop some little time ago. The primate has replied recently to this petition. He considers that such a degree might be misleading and would not be of any real value to Mr. Barker, but expresses the hope that "some means may be found of marking the public appreciation of what he cannot but call Mr. Barker's eminent services to sufferers." In his letter, the Archbishop goes on to say that from letters which have reached him he gathered that some at least of those who had signed the petition were under the impression that by holding a Lambeth medical degree *honoris causa*, Mr. Barker would become qualified to undertake medical or surgical practice from which, as an unregistered practitioner, he is at present debarred. This impression was a mistaken one, and the status acquired by registration is not given by the degree which the petitioners invite him to confer on Mr. Barker. That being so, he was at a loss to know in what way Mr. Barker's assistance would be made more generally available by his holding a Lambeth medical degree, unless it were by leading the public to suppose that he possesses the technical qualifications of a registered practitioner. The popular use of the title "doctor" in connection with his name would, the primate imagines, have this probable result, but it would not be in accordance with facts.

Obituary.—Dr. C. Montagu Handfield-Jones, of Cavendish Square, London, W., died on June 25 last from heart failure, following a prolonged illness, at the age of sixty-five. He was educated at Rugby Schol, London University, and at the Medical School of St. Mary's Hospital, where he had a very successful career as a student and where he was afterward lecturer on midwifery and diseases of women. He had been assistant physician at the Chelsea Hospital for Women and was consulting obstetric surgeon to St. Mary's Hospital and to Paddington Dispensary, and surgeon to in-patients at the British Lying-in Hospital. He was examiner in midwifery and the diseases of women for the University of London, the University of Cambridge, and the Victoria University. An ex-president of the Harveian Society and of the Obstetrical Section of the Royal Society of Medicine, he had contributed largely to various professional journals and to works on obstetric medicine and surgery.

OUR LETTER FROM BELGIUM.

(From Our Own Correspondent.)

LIÈGE, July 6, 1920.

Medical Congress of Brussels.—Instead of September 30, 1914, it was not until May 19, 1920, that the Fourteenth Congress of French-speaking Physicians opened at Brussels after six years' delay. After the sufferings of the war which were borne in common, this reunion of French physicians had the characteristics of very close brotherhood. Among the participants at the opening of the first meeting, which for the first time since the establishment of peace reunited all the French, French-speaking Swiss, and Belgian physicians, were also English, Danish, and Dutch friends.

Her Majesty the Queen of the Belgians had accepted the presidency of the opening meeting, and the President, Henri Jean, gave in his inaugural address a heartfelt tribute to the charitable devotion of this sovereign. He spoke in this address of the progress of medicine which was becoming more and more a pure science, and noted the progress made through the study of physiological chemistry applied to the humeral theory, the problems of anaphylaxis, the rôle of vitamines, and the organic reactions.

A subject in the program which was brilliantly discussed by MM. Hayet, Etienne, Vaquez, and Laubrez was the treatment of cardiovascular syphilis. MM. Zunz, Chauffard, Linossier, Guy Laroche, and Grigaut made extensive contributions to the very timely question of lipoids in therapeutics. Another address was on the therapeutic value of artificial pneumothorax, which was the subject of an interesting discussion by MM. Burnand, Dumanet, Kuss, Dezscheid, and Geeraert. In each of these three sessions one of the well-known professors in the Belgian Faculty delivered an oration of a general character. The first of these was Malvoz, who spoke at length on "Measures of Antivenereal Prophylaxis." Then Bordet, whose important book on immunity has just been published, discussed the "Coagulation of the Blood in the Light of New

Physiological Discoveries." Finally, Brachet, after discussing the history of the theory of heredity, paying special tribute to Darwin and Lamarck, spoke of the general manifestations and special aspects of heredity. The author of this marvellous work of ontogenesis was well qualified by his personal researches to speak on this vast and difficult problem. He recalled in moving terms all that Belgium might gain from Latin influences, and dwelt from the point of view of ethnology on the Franco-Belgian fraternity which was manifested even in scientific matters.

Balneological Stations in Belgium.—The indifference of the public authorities has been very prejudicial to the spas of Belgium, all the more as the most important of these installations were ruined during the occupation. Nevertheless Belgium has thermal springs of the first importance. The Academy of Medicine has, therefore, devoted several meetings to this question, at which M. Moeller spoke especially of Spa, Chaudfontaine, and Ostende. The waters of Spa are rich in iron and carbonic acid. This combination makes them very suitable for the digestive passages, and at the same time they are very useful in anemia. The waters of Spa are also efficacious in heart disease, having a value at least as great as those of Nauheim. A third indication is arthritis and all its complications. Mud baths such as are in use at Spa have a very favorable action in rheumatism.

M. Moeller then spoke of the baths at Chaudfontaine, and urged that the Government should grant a subsidy to a committee which had been formed at Liége to restore this station. The waters of Chaudfontaine are of an undetermined character. They have a temperature of 36° to 37° C., they are indicated in slow convalescence, and in certain nervous and rheumatic affections their value has been conclusively demonstrated.

Ostende suffered relatively little during the war, but it will take some time before strangers will find their way again to this resort. A project is under way to construct a bathing establishment, which is very necessary if treatment shall be carried out in a rational way. At the same time it will be necessary to complete the drilling operations intended to increase the flow of thermal water (22° C.) from the spring which is situated in the center of the city.

After the international conference at Monaco, where Terwagne represented La Société Belge d'Hydrologie et de Climatologie, it was only right that the Academy should concern itself with this question, especially in view of the fact that the next International Congress of Hydrology will be held at Brussels.

INFECTED APICES OF TEETH AND PYORRHEA ALVEOLARIS.

To the Editor of the Medical Record:

Sir:—In an article with the above title published in Medical Record July 10, 1920, the following statement occurs, among not a few to which I might take exception. To those cited below I am inclined to give my adhesion:

"The dentist can restrain the decay of teeth, diseases of the gums, and the infected areas of some roots, but these inhibitory treatments do not insure immuunity from recurrence if dental and bodily hygiene are neglected."

"It is not true that 'a clean tooth never decays.' Many an individual who has never used a tooth brush will show a perfect set of teeth."

In view of much that is written at present, in regard to the subject of pyorrhea alveolaris, which is in my judgment, faulty and indeed, false, I consider it desirable to quote some important truths. The sacrifice of many teeth, because of the exaggerated opinion that they cause serious disease in other organs, should be called a halt to and it is none too soon.

Beverly Robinson, M.D.

FAME AND PROFESSIONAL LIBERTY.

To the Editor of the Medical Record:

Sir:—Dr. S. Adolphus Knopf is to be congratulated upon the support and the encouragement his effort to honor American medicine by proposing a medical candidate for the Hall of Fame is receiving from the profession at large. Side by side with this effort there has been attempted another one designed to spare the medical profession from a distinction of a character the reverse of that which Dr. Knopf is endeavoring to confer upon it. For some reason this undertaking is receiving neither support nor encouragement though intended for the benefit of the members of the profession still living and as yet at large.

The candidates proposed by Dr. Knopf practised their profession unhampered by laws overruling their judgment and jeopardizing their liberty as well as besmirching their character. In this respect they enjoyed a distinction still attaching to the practice of medicine in every civilized country except our own.

Whether or not Dr. Knopf succeeds in his endeavor he has at least tried to put a representative medical man in the Hall of Fame. All that can be said of the effort coincident with his is that it has helped to keep one or more men of this type now practising medicine out of jail.

John P. Davin, M.D.

4. Specific Aortitis. William D. Reid.

4. Specific Aortitis. William D. Reid concludes from his study of the subject that syphilitic disease of the aorta is one of the most common and most serious findings in all cases of acquired syphilis. The lesion is essentially a mesaortitis, and a manifestation of active syphilitic disease; its conception as a parasyphilide being made untenable by the discovery in 1906 of the spirochete directly in the aortic lesion. The aortic process frequently extends to the aortic cusps, and Warthin has shown that relatively often there is an accompanying myocarditis of spirochetal origin. Aortic roughening, aortic regurgitation, dilatation or aneurysm of the aortic arch, and angina pectoris are common in

syphilitic aortitis. Aortic or mitral stenosis is of exceptional occurrence in connection with specific aortitis. Non-syphilitic forms of aortitis are rare. Many cases may be called latent in that symptoms are absent. Such cases are commonly undiagnosed until disclosed, perhaps, in a routine roentgen examination. There is no one point on which a diagnosis should be based, but only after a study of all the facts in a given case should a decision be rendered. Every case of cardiac disturbance of obscure origin, especially if the patient be a young adult and if there are signs of involvement of the aortic valve, should promptly suggest the probability of syphilitic causation. A positive Wassermann reaction is of confirmatory value, but is frequently absent. Roentgen examination, though unreliable in early cases, gives, perhaps, the most reliable findings. Specific aortitis evidences a tendency to progressive impairment of the heart and aorta and is, therefore, of serious import. Treatment should be directed primarily toward killing the spirochetes in the aortic lesions. Decomposition of the heart is to be treated as in that of non-syphilitic origin. Early diagnosis is imperative, and there should be a greater willingness on the part of clinicians to make a tentative diagnosis of specific aortitis and to resort to a therapeutic test.

8. Treatment of Tuberculosis. Benjamin S. Paschall.

2. **Diagnostic Tests in Hay Fever and Asthma.**—William Scheppegrell holds that in making the diagnostic test for hay fever one is guided in the selection of the pollen extract, by the location. It is, therefore, necessary to know the hay fever plants to which the patient is exposed, the representative biological group being sufficient in most cases. East of the hundredth meridian, one must test for the grasses, ragweed, and chenopods. West of this meridian, the tests should in addition also be made in the Rocky Mountain and Pacific States, since, although the ragweeds are uncommon, there are other members of the ragweed or Ambrosiaceæ group, such as the gærtnerias, marsh elders, Iva, and cockle burs, which respond to the same test and similar immunizing methods. In making the diagnostic test the writer has standardized the method, which, in a series of over a thousand cases, has given results which are accurate as regards the nature and degree of the sensitization, and reliable as a guide to the immunizing doses. Five units of the extract of the selected pollen, of the strength of one hundred units to the cubic centimeter, are injected into the skin, and the reaction determined in twenty minutes, and recorded on a percentage basis. A marked wheal, two or more centimeters in diameter, is recorded as 100 per cent.; one centimeter, 50 per cent., etc. While this is an arbitrary scale, it is valuable for gauging the size of the dose and for purposes of comparison, and is much more definite than such terms as mild, marked, or severe. The record of the diagnostic test is placed at the head of the clinical chart for each patient, so as to form a constant guide in administering the immunizing doses. A mild reaction indicates a proportionate tolerance of the pollen extract, and a marked reaction that caution should be used in increasing the doses of the pollen extracts. The record of the test also indicates the probable maximum dose required for desensitization. In patients of 90 per cent. reaction or over, 200 units is the maximum dose, and should be reached by gradually increasing doses. In those marked 60 per cent. the maximum dose is 600 units, and others in proportion. In the writer's last series of cases, in addition to the tests for sensitization to the various groups of pollens to which the patient is exposed, he included the test for a vaccine composed of the following microorganisms: Bacillus Friedlander, Micrococcus catarrhalis, pneumococcus, Streptococcus pyogenes, Staphylococcus aureus and albus. If there is a marked reaction to the intradermal injection of this vaccine it is used as a part of the immunizing process, and the degree of the reaction, as in the case of the pollen extracts, forms a guide to the size of the injections.

7. **Pleural Disease in Infants and Children. With Special Reference to Empyema.**—Harry Lowenburg, discussing the subject from the pediatrist's point of view, draws the following conclusions: (1) Surgeons and surgery have failed to give a definite method for the treatment of empyema. (2) Their right to preempt this disease is therefore denied. (3) A correct diagnosis as to the location of pus must precede all methods of treatment. (4) No patient should be operated upon until the evidences of pneumonia have passed and until the temperature has subsided and the pus has become thick. (5) Aspiration should precede permanent drainage, if there is mechanical interference with breathing, until the conditions mentioned above have been met. (6) Neither thoracotomy nor costatectomy *per se* offers any special advantage to the patient if indifferently performed. (7) The size of the opening is not nearly so important as the position of the opening. (8) Thorough drainage with proper irrigation of the infected area or areas, with a minimum amount of trauma, is desirable. (9) For this reason alone thoracotomy is to be preferred to costatectomy. (10) Personal experience would seem to indicate that multiple thoracotomy is the operation of choice. (11) A reasonable amount of pneumothorax in the absence of pneumonia is negligible.

10. **Prevention and Treatment of Weakfoot in Children.**—Percy Willard Roberts holds that if, through mechanical support and muscle training, the balance of the child's foot is maintained through the period of growth, there will result a normal foot, architecturally correct, and muscularly strong enough to meet all the demands that may be made on it in the years to come. There are three factors commonly at work to disturb the fulfillment of Nature's plan for the formation of the foot, namely, improperly designed shoes, unequally developed leg muscles, and a deviation in the normal mechanical relations between the tarsus and the leg. Perhaps the most important single factor in the development of a normal arch is the maintenance of the upright position of the os calcis during the period of growth. In some cases it is necessary only to raise the

inner border of the heel of the shoe to insure this result. In others, some firm mechanical appliance capable of grasping the heel will be indicated. It is the custom of the day, when a child has weakfoot, to put in the shoe a plate which presses up the arch. In the light of the writer's experience this would seem to be both psysiologically and mechanically wrong. The desired correction can be much more readily obtained by an apparatus whose effective force is applied directly to the heel, and the permanence of the results will be much more certain. Much can be done toward maintaining the proper alignment of the bones of the foot by muscle training; but the use of this measure must of course be deferred until such time as the child is old enough to cooperate intelligently; therefore, the question of shoes takes second place in any reasonable scheme of prophylactic supervision of foot growth. Children's footwear should be selected with an intelligent understanding of the needs of the growing foot. The popular idea that the anterior part of the shoe should swing inward—a design so often seen in so-called "orthopedic" lasts—is based on an entirely erroneous conception of the normal foot. About two thousand tracings of normal feet were collected by the American Posture League from various parts of this country, Japan and India, among which were many outlines of feet that had never worn shoes. Careful examination of these by means of a geometric scale revealed the fact that there exist three distinct types of feet, not merely one, as formerly supposed. These may be designated as the "straight," the "inflared," and the "outflared" foot. Unfortunately, there is no record of a similar study of children's feet, and until scientific data are available one must be content to treat the child's foot on more general principles when it comes to the selection of shoes, bearing in mind that compression of either the outer or the inner borders of the feet is to be avoided. The writer describes a plate which he has devised for the comfortable maintenance of the upright position of the os calcis, or its rotation outward if there is an inclination to pronation.

6. Some Racial Problems, Social Evils and Modern Crusades. Robert B. Wild.

3. Bone-Grafting of the Fractured Mandible.—Gilbert Chubb reports a series of sixty consecutive cases of bone-grafted mandibles, of which all but two were free autogenous grafts from the ilium. Fifty-one possessed edentulous posterior fragments and in forty of these the loss involved the region of the angle. In sixteen of the latter the loss involved the ascending ramus also. Firm bony union was obtained in fifty-six of the cases, 93 per cent. of the series. The graft and jaw fragments were so trimmed as to fit accurately end to end, with the largest obtainable areas of exposed vascular bone tissue held in close contact by firm wiring. The close apposition results in early bony union, while the firm fixation allows of the bones being subjected at once to some degree of muscular strain without fear of displacement, thus leading to the early consolidation of the primary union. In over 60 per cent. of the successful cases the union was of ivory hardness on the final removal of the splints, three to four months after operation.

6. Some Racial Problems, Social Evils, and Modern Crusades.—Robert B. Wild believes that the need for a clear appreciation of the factors involved in racial evolution is shown by many modern movements designed to improve the conditions of life, the welfare of the individual, and to produce a strong and virile race. On every hand there are crusades against predominant forms of racial degeneration. While he is far from wishing to make any attack upon these crusades, and least of all upon sincere, well-meaning, and often altruistic persons who lead them, he thinks it important to consider their racial as well as their individual effects. The welfare of a particular individual may not always be coincident with the best interests of the nation or race to which he belongs. After discussing the regeneration of the race, tuberculosis and cancer contrasted, venereal disease, eugenics, drug addiction, the effect of alcohol and other drugs on the race, the writer concludes that probably neither caffeine nor nicotine is a serious handicap to the nation at present, for competitive nations are equally affected by these addictions. If the use of these drugs enables more and better work to be done and diminishes the dependence of old age by an earlier wearing out of the arterial tissues the nation will gain at the cost of the individual, and in peace as in war the welfare of the individual should be sacrificed for the good of the race. He suggests that it is necessary for medical men to take a broad and unsentimental view of the issues with which they will be confronted in their work. If in the future the work of a medical man is to be more preventive than curative he will have to think more of the community and of the race than he has done in the past without thinking less of the individual.

7. Chemistry. Prof. Arthur Smithells.

2. The Place of Preliminary Science in the Medical Curriculum.—Sir George Newman, in his introductory address as president of the Section of Medical Education of the British Medical Association, at the recent annual meeting of that body, said the form and content of the medical curriculum are dependent on two principal factors: (*a*) the advance of our knowledge of the science of medicine, and (*b*) the demands made upon the practitioner of the art of medicine. The curriculum must incorporate the principles of medicine as interpreted in current knowledge. It must also comprehend its practice in relation to the needs of the time and the art of the practitioner. The expansion of applied medicine and the widening of the demand which the community makes on the medical man must thus find its counterpart in the curriculum. The establishment of clinical teaching units is but an expression of the growth of integration. By gradual evolution of this unit method over many years there has come to be recognized the necessity of further development in the curriculum. It is not revolution we need, but reform, and even reformers must have regard to the facts (*a*) that the scope and character of secondary education is not yet settled, (*b*) that medicine itself is in a transitional state, and (*c*) that the public medical services has not yet crystallized itself. Speaking generally, however, it appears that the main reforms needed in the medical curriculum are four: 1. A lightening of the curriculum at both ends—in other words, fuller preparation in science before entrance to the medical school, and a postponement of instruction in certain specialties and in general practice to the post-graduate period; 2. A fuller study of the sciences preliminary to medicine and a nearer application of these subjects to clinical work; 3. Development of clinical teaching of university standard, particularly in relation to the beginnings of disease, the science of prevention, the closer integration of various forms of clinical practice and of clinical with intermediate study, concentration on the protean diseases of tuberculosis, venereal, malaria, malignant disease, and an understanding of the social side of therapeutics, as well as the social aspects of disease; 4. There is need of further State aid, with a minimum of State control.

8. A Biological Study of Hemolytic Streptococci from Throats of Patients Suffering from Scarlet Fever. Preliminary Report. Walter P. Bliss.

1. The Significance of Syphilis in Prenatal Care and in the Causation of Fœtal Death.—J. Whitridge Williams, in preparing material for his presidential address "Upon the Limitations and Possibilities of Prenatal Care," presented before the American Association for the Prevention of Infantile Mortality, in 1915, became convinced that the only way in which the problem could be approached with any hope of effective solution was by determining the Wassermann reaction in every pregnant woman who registered in the dispensary, and subjecting her to intensive antisyphilitic treatment whenever it was positive. This work was begun in April, 1916, and the present paper is based upon the critical study of 302 fetal deaths occurring in 4000 consecutive deliveries between that period and December 31, 1919. Attention is directed to the fact that the material differs from that which may be collected in many other cities, somewhat more than half of the patients being black. Thus, in 4000 cases under consideration, there were 1839 white and 2161 black women, in whom positive Wassermann reaction was present in 2.48 and 16.29 per cent., respectively. This incidence, however, did not exhaust the possibilities of syphilis, as there were 105 additional women in the series in whom the Wassermann reaction was negative, but in whose history some mention was made of syphilis. Of the 302 dead babies 212 came to autopsy. In the former are included not only those dying at the time of labor, or during the two weeks immediately following it, but also those dying during pregnancy from the time of viability onward. Of the 302 deaths 99 occurred in white and 203 in black infants, an incidence of 5.4 and 9.4 per cent., respectively; while 157 occurred at the time of labor or during the first two weeks of the puerperium, and 145 were in premature children. Syphilis was noted in 104 cases, in 89 of which the diagnosis was confirmed by autopsy with the demonstration of spirochetes in the fetal tissues; while in the remainder it was made from the presence of syphilitic lesions in the placenta, associated with a positive Wassermann on the part of the mother. The causes of death are as follows: Syphilis, 34.44 per cent.; dystocia, 15.20 per cent.; toxemia, 11.55 per cent.; prematurity, 10.59 per cent.; cause unknown, 8.61 per cent.; placenta previa and premature separation, 5.28 per cent.; deformity, 3.64 per cent.; eleven other causes, 10.69 per cent. Upon analyzing the figures in the summary of the causes of death it is seen that 89.3 per cent. of the deaths are attributable to seven groups of causes, of which syphilis is the most important, as it accounts for 34.44 per cent. of the total number, which is almost as high as the mortality for the next three groups combined, dystocia, toxemia, and prematurity, which were responsible for 37.34 per cent., or only 3 per cent. more than syphilis. Consequently, it is apparent that if it were possible to eradicate syphilis as great a reduction in fetal mortality should be effected as by doing away with all fetal deaths due to the various accidents at the time of labor, toxemia, and prematurity combined.

8. A Biological Study of Hemolytic Streptococci from Throats of Patients Suffering from Scarlet Fever.—Walter P. Bliss, in this preliminary report, summarizes his study as follows: (1) In a study of 25 strains of *S. hemolyticus* isolated from the throats of patients with scarlet fever, 20 or 80 per cent. were agglutinated by four different antistreptococcic sera made with streptococci isolated from scarlet fever cases. (2) None of these strains were agglutinated by five antistreptococcic sera of nonscarlatinal origin (except in the few instances noted). (3) But three of seventeen strains of nonscarlatinal origin were agglutinated by these three sera of scarlatinal origin, and these three may have been either atypical scarlatinas or scarlatinal contacts. (4) Certain differences in cultural characteristics, particularly in the fermentation of carbohydrates, were noted. From this study, therefore, it would appear that a great majority (80 per cent.) of strains of *S. hemolyticus* isolated from the throats of patients with scarlet fever belong to a specific biological type as determined by the reaction of agglutination. It is possible that the heterogeneous strains found may be accidental dwellers in the throat and that a more careful selection of colonies may reveal a still higher proportion of unit type organisms.

La Presse Médicale.

April 28, 1920, xxviii, 26.

Migraine.—Pagniez and Nast have continued a line of investigation on the anaphylactic nature of migraine, their earlier reports having been noted editorially at the time in the MEDICAL RECORD. It was shown that in the predisposed subject certain substances like chocolate could cause a migrainous anaphylaxis, and also that peptone has some power toward preventing such anaphylactic crises. It is not claimed that all migraine or even the greater part is of this nature, but a type exists which can be produced at will. Among the causes which operate in this type are certain articles of diet, alcoholic beverages, great muscular fatigue and emotions—so that among such cases personal hygiene will protect the victim. It does not follow that the attack at once succeeds the indiscretion, for as a rule there is a period of inoculation. This may range from a few hours to a day and upward. Again the cause does not always produce the effect, for there are days on which the subject seems immune. There is therefore a periodic factor which enters into the personal equation, and the subject may at times give himself license to indulge in this or that article of food, etc., for days at a time. In a given case the subject was born to migraine and suffered early in life from the ophthalmic form. This man discovered that a little peptone before meals had some prophylactic value. The attacks were decidedly less frequent and when the peptone was intermitted the frequency returned. He also soon learned that chocolate, especially when served with milk, increased the frequency and severity of the attacks. Under observation of the authors it was shown six times in succession that chocolate precipitated a migrainous attack, the blood showing the hemoclastic crisis which is believed to characterize anaphylaxis. It was also shown that chocolate could not invariably produce an attack. Under observation the subject used peptone systematically before meals, and after a certain period chocolate failed to produce the anaphylaxis after an appropriate test. The immunity was not permanent, for when the peptone was discontinued chocolate produced the crises as before.

Hygiea.

April 30, 1920. lxxxii, 8.

Spanish Influenza in the Sahlgren Hospital.—Wallgren states that from July 12 to December 31, 1918, 1311 cases of influenza were received into this institution. Of this number 94 died within the first 24 hours. The total mortality was 30.4 per cent. The men showed the higher death rate and 20 to 30 was the age period most favorable for mortality. In 77 per cent. pneumonia was present with a death rate of 50 per cent. There were 86 cases of empyema with a mortality of 56 per cent. Cardiac disease and pregnancy aggravated the prognosis. Those who took to bed early in the disease withstood the latter better than the others. No plan of treatment was isolated as superior to others. Pfeiffer's bacillus was not found.

Chancroidal Infection of a Year's Duration Cured by a Specific Serum.—Reenstierna describes an interesting case in which a chancroidal bubo, having suppurated, gave rise to a persistent ulcer which resisted all attempts to heal it, including the paquelin. The absence

of other pathogenic factors was shown by the autoinoculation test, which was positive, and the presence in pure culture of the Ducrey bacillus. Ulceration extended from the spine of the ilium to the substance of the scrotum, and the greatest length of the ulcer was nearly 10 inches. There was considerable constitutional reaction, including fever. The cutireaction of Ito with streptobacillary vaccine was positive, and after a single injection for therapeutic purposes there was a notable improvement. This injection sent the temperature up to nearly 104, and a second smaller one still higher. No other injections are mentioned and healing occurred in a surprisingly short time. Only airol powder was used as a dressing.

El Siglo Medico.

April 17, 1920, lxvii, 3462.

Case of Chronic Hemorrhagic Sepsis.—Munoyerro y Calvin relates the history of a case regarded by him as interesting and extraordinary. His communication is only a preliminary one. The beginning of the episode was in the fall of 1915, long before the pandemic of influenza, and the author has been unable to find a parallel in literature. The patient was a woman of 26, with negative antecedents. When first attacked there was a temperature of 42.2 C. The condition became confirmed with periods of remission and exacerbation and the author did not personally see the patient until some months had elapsed. He found her in bed in fair general condition, regularly nourished and remarkably free from symptoms of an objective character. Physical examination discovered nothing. There was a temperature of 30 C with attacks of nosebleed, the patient was pallid with a saburral tongue and there was little else to be learned. A provisional diagnosis of tuberculosis was made but abandoned soon after. The condition has persisted to the time of writing and the author submits the following as the summation of the symptomatology: Fever without chilliness, the highest temperature being 39 C. She has not been afebrile for a single day. But if any food articles are given other than milk and fruit juices the temperature may shoot up to 41 and upward. Even the blandest starchy foods cannot be tolerated. Hemorrhages occur—epistaxis and rectal hemorrhage (no hemorrhoids) and at one time hematuria. On the other hand there has been no menstruation for 2 years. Albuminuria is one of the constant symptoms. There are digestive disturbances—saburral tongue, anorexia, nausea and frequent vomiting. The woman is notably hysterical with anesthetic zones and absence of pharyngeal reflex. Finally there are insomnia and cephalalgia. It is evident that in such a case only a blood examination can clarify the situation and the case has been extensively studied from this angle. One by one various blood states have been excluded, including the acute fevers and tuberculosis. The sole positive find has been a bacillus originally described by Fraenkel and Pielsticker as belonging to the group which causes hemorrhagic sepsis which the author concludes to be the cause of all the mischief. An autovaccine prepared from this germ has been employed and seems to have caused a sharp diagnostic reaction. The affection seems to have been favorably modified by the vaccine treatment, but the recurrence of severe reactions has caused it to be abandoned for the time.

Brazil Medico.

April 10, 1920, xxxiv, 15.

Cocainomania in Brazil.—Vieira de Almeida, after a narration of the early history of cocaine addiction in which few Brazilian authorities are quoted takes up the subject as it is seen in Rio and Sao Paulo. According to the secular press there exists in the Paulistic capital a club of cocaine addicts, known as the *Club de Morte*. In local parlance cocaine is termed *Pó*, a word of uncertain derivation (which recalls the fact that in New York it is known as "snow," "happy dust," etc.). The sale of the drug is largely in the hands of unscrupulous people, who make a special industry of it and peddle it about. The *Club de Morte* is known to have lost five of its members recently by death, so that it has already qualified for its name. Two Rio Chinese are mentioned as dealing jointly in the two drugs—opium and cocaine. Each partner is responsible for one of the two drugs. In the same city a barkeeper is mentioned as having sold cocaine as a side line. A certain barber is said to have smuggled several kilograms of cocaine into Rio from some European port. The demimondaines are among the chief consumers of the drug, and the night bars frequented by these women serve as centers of distribution. The laws against the sale of cocaine appear to be general and directed against the illegal sale of poisons in general. There is no mention of special narcotic laws with the exception of a special penalty in the Sanitary Code of the State of Sao Paulo for the sale of "anesthetics," which includes cocaine and opiates. The laws against the sale of poisons are clearly intended for the prevention of assassination rather than addiction. Since no statistics of addiction are mentioned which correspond to the records of Bellevue in New York we can obtain no idea of the actual amount of damage done to the public health; but according to the daily press addiction is widespread and there is urgent need of a crusade against certain pharmacists and other illegal venders of the drug.

Tonsillar Sepsis.—The question of the existence of a septicemia which originates in the tonsils and is primary and quite distinct from other affections is discussed by de Rezende. Septic tonsillitis may have a varied incidence, and may develop after any clinical form of inflamed tonsil. The epidemic form due to the *Streptococcus hemolyticus B.*, which has been seen repeatedly in North America, is also known to exist in Sao Paulo. The tonsil is enough of a menace on this count alone to justify its routine extirpation. This conclusion is reached without any regard for the existence of numerous other infections which proceed from the tonsil, as acute rheumatism, nephritis, appendicitis, the slow form of endocarditis, etc., etc.—*Brazil Medico.*

Survival of Quadruplets.—Pinard, having come upon quadruplets aged five years, took pains to learn the particulars of their accouchement and obtained the testimony of the attending midwife and obstetrician. The former, who, of course, first saw the case, recognized multiple gestation. Labor lasted two days. The first child presented by the vertex and was extracted with forceps. Twenty minutes later another bag of waters ruptured and the second child presented, breech first. A third bag ruptured and this infant also presented by the breech. The fourth child presented by the vertex. Postpartum hemorrhage made it necessary to deliver the placenta, which was single, although associated with four gestation sacs. The babies weighed in the order of birth 1,900, 1,950, 2,000 and 2,100 gms. Credit for the survival was due alike to the faithfulness and intelligence of the midwife, accoucheur, and parents, and the children have thus far never been ill.—*Gazette des Hôpitaux.*

Malaria in the Balkans.—According to Dr. Regina Flood Keyes of Buffalo, N. Y., an American Red Cross physician who has lived in the Balkans for several years and who has been decorated by the French, Greek and Serbian governments for operations performed under heavy bombardment, the backwardness of the Balkan peoples is attributable to two causes, sand-fly fever and malaria. "The Red Cross fight against typhus, smallpox, cholera and sex diseases in the Balkans attracts much attention in the press," says Dr. Keyes, "but our real work out here is the struggle to down malaria. More British soldiers died or were incapacitated by malaria in the Struma Valley during the war than were killed in the taking of the Grande Couronne. The whole littoral of the eastern Adriatic from Fiume down to Avlona is a hotbed of malaria and sand-fly fever, while the northern shore of the Aegean from Salonica to Constantinople is even worse. America, if she is going to play her rôle in the world, must do for the Balkans what she did in the Panama Zone. These peoples must be taught drainage, how to kill the mosquito and to maintain domestic sanitation. It is a work of years, but we have made a good start in the last thirty months. Malaria causes the all too obvious despondency of the Balkan peoples."

Book Reviews.

GENERAL AND DENTAL PATHOLOGY, with Special Reference to Etiology and Pathologic Anatomy. A Treatise for Students and Practitioners. By JULIO ENDELMAN, M.S., D.D.S., Professor of Special Dental Pathology, College of Dentistry, University of Southern California; Editor of the Pacific Dental Gazette; Member of the Southern California Dental Association, the California State Dental Association, and the National Dental Association; Corresponding Member of the Société Odontologique de France, Honorary Member of the Sociedad Odontologica de Chile, etc., and A. F. WAGNER, A.M., M.D., Professor of General Pathology, College of Dentistry, University of Southern California; Pathologist and Autopsy Surgeon of the County and City of Los Angeles; Member of the Los Angeles County Medical Society, California State Medical Association, American Medical Association, etc. With 440 illustrations, of which 340 in the Section on Dental Pathology are original, and four colored plates. St. Louis: The C. V. Mosby Company, 1920.

THIS is a happy combination of general and dental pathology, with rather more of the former than is usually found in books intended for dental students and practitioners, which is a particularly good feature of the work. The tendency hitherto, now happily diminishing, has been for dental students to get merely a smattering of general pathology, hardly more than sufficient to give them the vocabulary of the science, and then to plunge right into the special part, ignoring the fact that no one can acquire a real knowledge of special pathology in any branch unless the study is firmly grounded on the foundation of general pathology. In this book of about 800 pages, the first 212 are devoted to general pathology and the following 573 to special dental pathology. This is sufficient to give the dental student all that he absolutely needs to know of general pathology, though, of course, it will not meet the requirements of the medical student. The latter, however, might with profit study the section on dental pathology in this book, for it will supply him with knowledge that he cannot find presented so completely and so clearly in the ordinary works on general pathology. The illustrations in the dental section are capital; they are from original sources, well reproduced from photographs and *x*-ray pictures, and clearly printed on calendered paper. At the present time, when the danger to health and life from foci of infection in teeth and alveoli is so fully recognized—even exaggerated—it behooves the medical man to have more than a mere smattering of dental pathology, and the necessary knowledge can be easily and pleasantly acquired from this book.

COLLECTED REPRINTS FROM THE GEORGE WILLIAMS HOOPER FOUNDATION FOR MEDICAL RESEARCH. Volume IV, 1918-1919. San Francisco: The Department of Research Medicine of the University of California Medical School.

THIS volume contains twenty-nine reprints of articles that have been published, chiefly in 1919. A series of six on the metabolism of bile acids are especially noteworthy, while another series of four on the effects of chloroform upon the liver are also worthy of comment. The Department of Research Medicine has a very large staff both of permanent and volunteer workers, and apparently carries on a large amount of research, which presumably is represented only to a comparatively small extent by the work here presented.

WHEELER'S HANDBOOK OF MEDICINE. By WILLIAM R. JACK, B.Sc., M.D., F.R.F.P.S.G., Physician to the Glasgow Royal Infirmary, Lecturer in Clinical Medicine in the University, Glasgow. Sixth Edition. Edinburgh: E. and S. Livingstone; New York: William Wood and Company, 1920.

THIS new edition does not show any marked changes; still, there are some alterations in the arrangement of the topics, and a few new articles, on Landry's paralysis, caisson disease, compression paraplegia, and myasthenia gravis. The editor has added a new section on the "Medical diseases of the war," containing articles on Trench fever, Spirochætosis ictero-hæmorrhagica. War nephritis, Trench foot, and War neuroses (shell shock). There is a large amount of material condensed in this little volume, and the book can be strongly recommended to students preparing for examinations in Practice.

THE DISEASES OF INFANTS AND CHILDREN. By J. P. CROZER GRIFFITH, M.D., Ph.D., Professor of Pediatrics in the University of Pennsylvania, Philadelphia; Physician to the Children's Hospital of Philadelphia, and to the Children's Medical Ward of the University Hospital; Consulting Physician to St. Christopher's Hospital for Children, Philadelphia; Corresponding Member of the Société de Pédiatrie de Paris. With 436 illustrations, including 20 plates in colors. Two volumes. Philadelphia and London: W. B. Saunders Company, 1919.

THIS comprehensive treatise on pediatrics, with its numerous illustrations, charts and tables, forms a useful addition to the equipment of the general practitioner and the pediatrician. The author has succeeded admirably in his avowed purpose of reviewing the subject of medical pediatrics in as complete a manner as seemed desirable without attempting to make it encyclopedic. Surgery and the special branches with the recognition of which physicians treating the diseases of children should be more or less familiar are included. Extensive footnote bibliographic references are given throughout the volumes, but no index of authors or collective bibliography. The index to the first volume comprises 26 of its 885 pages, while that of the second volume occupies 58 of its 657 pages.

The subject matter of Volume I is arranged in two divisions, each with its series of chapters. The first division covers general subjects (anatomy and physiology of early life; hygiene; breast-feeding; artificial feeding in the first year; foods other than milk; special named mixtures and proprietary foods; diet after the first year; diet in illness; characteristics of disease in infancy and childhood; symptomatology and diagnosis; morbidity and mortality; therapeutics in early life). The second division deals with diseases, including diseases of the new-born; infectious diseases; general and nutritional diseases; diseases of the digestive system.

Volume II continues the discussion of diseases, including diseases of the respiratory system; diseases of the circulatory system; diseases of the nervous system; diseases of the muscles, bones, and joints; diseases of the blood, spleen, and lymphatic glands; diseases of the ductless glands and internal secretions; and diseases of the skin, eye, and ear. Both the metric and the English systems of measurements are used throughout. The author has unfortunately deferred to the wishes of the publishers in the matters of spelling and punctuation, and so in a manner defaced what would otherwise have been many fair pages.

A TEXT-BOOK OF DERMATOLOGY. By J. DARIER, Physician to the Hôpital Saint-Louis, Member of the Academy of Medicine, Paris, France; Honorary Member of the American Dermatological Association, etc. Authorized translation from the Second Edition edited with notes by S. POLLITZER, Ex-President of the American Dermatological Association, Corresponding Member of the French Society of Dermatology and Syphilography, etc. Illustrated with 204 engravings and 4 colored plates. Philadelphia and New York: Lea & Febiger, 1920.

THE general didactic plan followed in the first edition of this useful work has been retained. A few sections have been rewritten and elaborated more or less in accordance with newer ideas or for other reasons, notable among these being those dealing with anaphylaxis, phagedena, the sarcoids, the gangrenes, the cutaneous atrophies, inguinal epidermophytosis, and the dermatomycoses. Other changes involve the review of the general interpretation of tuberculosis, congenital syphilis and the xanthomata. New paragraphs or chapters have been added covering the dyskeratoses, cutaneous diphtheria, the leishmanioses, the cutaneous leukemias, and the tophi of gout. The serodiagnosis of syphilis and the treatment with the arsenobenzols are brought up to date. Thirty-nine pages of the text are devoted to therapeutic notes, which are based on the author's personal experience. For quick reference this part of the book is of very practical value to the student or the inexperienced dermatologist.

Society Reports.

EIGHTY-EIGHTH ANNUAL MEETING OF BRITISH MEDICAL ASSOCIATON.

Held at Cambridge, June 25-July 2, 1920.

(From Our London Correspondent.)

National Health Insurance Act.—Among the affairs discussed by the representative body of the British Medical Association at its last session on June 29 was the question of the National Health Insurance Act. With regard to its effect on tuberculosis, Dr. Baskett of Rayleigh, Essex, moved a resolution calling attention to the slackening in the fall of tuberculosis mortality, resenting enforced association with a measure which, prima facie, seemed, and on strict investigation might prove to be, prejudicial to the national health, and instructing the council to institute an inquiry into the effect of the act upon the nutrition of the poor. Dr. Baskett said tuberculosis ran riot in Europe owing to the concomitants of poverty. It had been greater in this country since the insurance act, because that act had caused many people to become poorer, and their power of resistance to disease to become diminished. Dr. S. Noy Scott of Plymstock urged the necessity for investigation and said the tables produced by some county councils would not bear the light. Dr. Douglas of Fife contended that the main causes of tuberculosis in recent years had been the alteration in diet, principally through the shortage of fats, the large portion of the population that had worked in a vitiated atmosphere while making munitions, and the fact that the public health service had been crippled in this country by the medical profession doing war service abroad. The insurance act, whatever its imperfections, might do a great deal of good. Dr. Brackenbury of London said they might all agree that the insurance act was not performing the function which some of its short-sighted but enthusiastic admirers declared it was going to perform with regard to tuberculosis. "But for us to say," he continued, "that because the rise in tuberculosis mortality is coincident with the passing of a certain act of Parliament it has been caused by that act would be absurd." The resolution was defeated. The conference gave its support to the proposal that two medical men should become candidates for Parliament to watch the interests of the profession. Dr. H. B. Brackenbury of London was favored as one of the candidates. On the question of public health and poor law an opinion was expressed in favor of poor law hospitals being available for receiving paying patients who should be attended by their own doctors, and the council were instructed to inquire and report on the situation.

Honorary Degrees Conferred by Cambridge University.—In connection with the visit of the British Medical Association to Cambridge honorary degrees were conferred on June 29 upon the undermentioned members of the medical profession: Sir Thomas Clifford Allbutt, Regius Professor of Physic and president of British Medical Association; M. Jules Bordet, president of the Faculty of Medicine and director of the Institut Pasteur at Brussels; Dr. Simon Flexner, director of the laboratories of the Rockefeller Institute for Medical Research; Professor Piero Giacosa, Professor of Materia Medica and Experimental Pharmacology at the University of Turin; Sir George Henry Makins, president of the Royal College of Surgeons; Sir Norman Moore, Bt., president of the Royal College of Surgeons. The degree in each case was that of Doctor of Law (honoris causa) and was conferred by the vice-chancellor, Dr. Giles, Master of Emmanuel College. Four gentlemen were unable to be present to take their degrees, viz., M. Albert Calmette, subdirector of the Institut Pasteur at Paris; Dr. Harvey Cushing, professor of Surgery at Harvard University; Major-General William Crawford Gorgas, formerly Surgeon-General, U. S. Army, and Sir Patrick Manson.

The President's Address.—On the evening of June 29 in the Cambridge University Senate House the presidential address was delivered by Sir T. Clifford Allbutt, and was a review of medicine in Great Britain. Sir C. Allbutt is a charming and cultured speaker and his address abounded in witticisms and apt allusions. He said that when one turned to public medicine one was met by two chief problems which called instantly for solution—general practice and the voluntary hospitals. An official doctor, he said, would be as alert and as progressive as a country parson, whose service was not much kindled by the chances of promotion to an archdeaconry or a bishropic; while to shift an official doctor from place to place would be to cut the inner threads of those intimacies which they were now declaring to be the clues to the detection of diseases at their sources. Yet, as things were, the independent practitioner was isolated; even in a town he was apt to make a little orbit for himself, to drift out of intimacy, perhaps into some jealousies, with his brethren; he lacked mental incentive, and gradually let slip occasions of scientific reunion and renewal. Indeed, he could not readily leave home to attend public and scientific meetings, so that too often, as Morant complained, "Medical men do not think or express themselves in a statesmanlike way." His time even at home was so broken up that he lost the habit of study. He might leave his hospital school full of ardor and in rapid growth, but in practice his ardor cooled and he dropped into routine; or, at any rate, such was his peril, and so less and less might the doctor feel himself a member of a great profession; he might drift out of public affairs, his outlook and sympathies might shrink, his work become a trade, and his medical neighbor his "opponent."

Panel practice, he continued, for some time discredited by its hereditary taint of the club of infamous memory, and by the continual dearth of the means of its development, should, if duly provided, expand into a large, honorable, and even universal department of medical work; the terms of engagement were to be more liberal; the clockwork was complete. But how was the practitioner to rise to higher standards of modern science and skill when no means of investigating disease, or of making an intimate diagnosis, were provided for him? He was well aware that the modern methods of medicine depended on such means as *x*-rays, a battery of stains, and other cultural and biochemical apparatus; and not only an education in the use of these, but also the time to give to them. What should we think of a regiment of recruits called out to fight the enemy but unprovided with weapons or munitions? If the doctor were near a university center he could get blood tested for morphological elements, or for sugar, or for nitrogen content, excretions analyzed, bacterial examinations, and vaccines made, and so forth; but it was imperative that these opportunities, now confined to a few, should be universal. Moreover, if they were to be fruitful, the practitioner must consult personally with the scientist. These plants, then, and their staffs must be established in all districts, together with a much larger provision of cottage hospitals. Cambridge University and its sisters were sending out every year bands of young graduates quite competent to deal with disease in all its forms, and to use refined means of diagnosis, if those means were supplied. If not, how could they be blamed if they fell into some stagnant routine? In district laboratories panel work would be paid for by the Ministry of Health; for private practice a tariff of fees would be agreed upon. A considerable sum for the commencement of these local centers was contained in the stillborn budget of 1914. As to the voluntary hospitals, he omitted what he had written because the report of the Consultative Council had covered a much larger ground, and so ably that his passing reflections would be of little use. The dilemma between the lack of funds and the fear, almost an assurance, that public grants in aid would discourage private munificence might be avoided if, on proof of efficiency, grants in aid were offered in some proportion to the amount raised by voluntary effort. To range up the poor law infirmaries with other hospitals and schools would enrich our clinical fields beyond all anticipation.

Award of Prizes and Medals.—Immediately after the presidential address the association's gold medal of merit, awarded to the late Capt. N. G. Chavasse, was received by his father, the Right Reverend F. T. Chavasse, Bishop of Liverpool, who made a touching and

eloquent little speech. The Stewart prize was presented to Miss Harriette Chick, D.Sc., in recognition of her own work and that of the band of scientific women associated with her in the investigations into the means for preventing scurvy and beriberi in armies and among populations suffering privations. The Middlemore prize was presented to Dr. Harry Moss Traquair for his essay on perimetry, inclusive of scotometry, its methods and its value to the ophthalmic surgeon.

Surgical Treatment of Gastric Ulcer.—On June 30, in the surgical section under the presidency of Sir George H. Makins, a discussion was held on the surgical treatment of gastric ulcer opened by Sir Berkeley G. A. Moynihan and Dr. Charles H. Mayo. Sir Berkeley Moynihan, referring to the origin of gastric ulcer, said that most of the causes of this condition lay within the abdomen. However, he strongly advised a thorough examination of the buccal cavity for alveolar abscess, and so on. He believed that in the majority of cases medical treatment was ineffectual, because as commonly applied it was doomed to failure. He was of the opinion that withholding fluids for a few hours before operation was radically wrong, and especially so in the case of gastric ulcer. He gave large quantities of fluid before operation. Gastroenterostomy was the operation usually done for gastric ulcer, and for years it did a great deal of good, until it came to be used for all kinds of gastric ulcers. The operation was often badly done, and the cases were badly selected. Symptomatic diagnosis was not to be depended upon, and several instances were cited to prove this point. Chronic ulcer preceded carcinoma in not less than 10 per cent. of cases. Gastroenterostomy alone had been abandoned by Moynihan. The operation did not prevent recurrence of gastric ulcer or occurrence of carcinoma. It was to be regarded as the second best operation for this condition. He recommended the use of the finest catgut, that of silk or thread not being necessary. He thought Balfour's operation was good and he had learned much concerning this operation from the Mayos of Rochester. He pointed out that gastric ulcer was a more serious disease than was generally realized. Athletes in every branch of sport suffered from duodenal ulcer, none from gastric ulcer. These respective ulcers were found in different types of patients, as Hurst had shown. Early and correct diagnosis of gastric ulcer was the main thing. Gastric ulcer was rare and serious. According to his view there was only one operation for gastric ulcer, namely, partial gastrectomy. When this was done everything was done, and the patient was cured. Moynihan emphasized the necessity for paying the most exact attention to all details, for after all it was the little things that counted.

Dr. Charles Mayo said in part that gastric ulcer was more common in males than in females. According to the statistics of the Mayo Clinic, duodenal ulcer occurred four times more frequently than gastric ulcer. He insisted that the medical treatment was mainly dietetic. Duodenal ulcer rarely developed malignancy. Gastric ulcer was not caused by traumatism and perforation was not so serious as it was believed to be. The *x*-rays were the best means of diagnosis. A correct diagnosis could be made by this method in 95 per cent. of cases. Cancer of the stomach rarely occurred with high acidity. He described the technique of the operations for gastric ulcer employed at Rochester, Minn. Sherren's operation had been improved upon by Balfour. He laid emphasis upon the wisdom of using catgut sutures. According to the figures collected by Hunter of the New York Life Insurance Company the operative mortality of gastric ulcer was 3 per cent. over normal, while that of duodenal ulcer was less than normal.

Mr. Herbert Paterson said that from the clinical standpoint it was argued by some that gastrojejunostomy was solely mechanical and had no physiological effects. He held, however, that scepticism is a sure precursor of belief. Gastrojejunostomy was not a purely mechanical operation, but exerted a definite physiological effect. With regard to the contention that malignancy is not infrequently grafted upon a gastric ulcer he was skeptical. He believed that those ulcers which developed cancer were inherently malignant and, of course, this was not the case with the ordinary gastric ulcer. He put it that either malignant disease does not develop on gastric ulcer or gastrojejunostomy is a cure for cancer.

Mr. Burgess said that the object was to get rid of gastric ulcer, to abolish the pathological basis at the back of the ulcer, that is, the hyperacidity. In his opinion hyperacidity was best cured by gastroenterostomy. Gastroenterostomy alone was often insufficient, and the logical combination was excision of the ulcer and gastroenterostomy, of which the latter was the essential part. The most effective routine method was partial gastrectomy. Burgess thought that the physiological effect of gastroenterostomy had been proved up to the hilt. After dealing with the technique of the operation, he laid stress on the supreme importance of after treatment, of which careful diet and taking an alkaline were the fundamental features.

Mr. Charles Ryall was in favor of gastroenterostomy from the physiological standpoint. Conditions must be always considered, but he did not believe in laying down the rule that partial gastrectomy should be performed on all gastric ulcers. In his opinion the employment of the cautery was dangerous. Too great importance was attached to the possible connection between chronic gastric ulcer and cancer.

Dr. Finney began by apologizing for still wearing a uniform, and went on to say that his country had a good deal of difficulty in getting into the war and more difficulty in getting out of it. He remarked that he had been through all the gamut of operations, and failed in a sufficient number of cases to produce skepticism. Therefore, he was never cocksure, and thought it was unwise to lay down hard and fast rules. All cases should be judged by the conditions found. Finney also disbelieved in any sure method of diagnosis. He had opened the abdomen and even the stomach, and then didn't know whether an ulcer was there. As said before, he believed in performing the operation which was deemed to be best suited to the conditions found.

Vitamines.—Perhaps, on the whole, the most interesting discussion of the meeting was one held in the Section on Medicine, dealing with the position of vitamines in clinical medicine. Sir Humphrey D. Rolleston presided over this section. Dr. Gowland Hopkins, Professor of Biochemistry at the University of Cambridge, opened the discussion by reading a paper in which he pointed out that the modern conception of a deficiency disease was not, of course, based wholly upon a belief in the existence of vitamines. There might be quite other factors of deficiency in a diet which would produce clinical symptoms, but the hypothesis of vitamine deficiency played a large part in current views concerning the chief examples of the conditions to be discussed. The idea of existence of such substances as those called vitamines arose quite inevitably from the fresh facts concerning nutrition which were gathered by means of experiment and observation at about the beginning of the present decade. There should have been, as Hopkins had always maintained, nothing particularly startling about these new facts. It was always an assumption that proteins, fats, carbohydrates, and certain minerals represented the whole nutritional demands of the animal. Directly these constituents of food were fed really pure it was found that they were not. The only matter for surprise was that certain substances, produced like all others by the plant, should prove so important, though present in so small an amount. Professor Hopkins emphasized the point that in what he was about to say he refused to speak of the vitamine "hypothesis." Vitamines, though still of unknown nature in the chemical sense, were not merely hypothetical. In nearly every case that was to be considered it was, he admitted, still an hypothesis that the particular disease depended upon vitamine deficiency, but in respect to the broad aspects of nutrition as a whole, the importance of these factors was proven. But he had found that there was at the present moment some skepticism concerning the whole question, particularly perhaps among certain members of the medical profession. The fact that he had met it lately in high quarters accounted for the particular direction he was giving to his opening remarks which might seem unnecessarily defensive. Some of this skepticism had been stimulated by or was a protest against quackery;

the quackery which always dogged the footsteps of honest scientific work and the promulgation of sound views concerning human nutrition. It was well, indeed, that the subject about to be discussed should be approached critically, but disbelief in the very great importance of qualitative deficiencies in the diet, quantitatively of small moment in the production of nutritional errors was to be deprecated. Not long ago, in a professional discussion, a physician whose authority in medicine is of the highest, spoke of the "vitamine stunt." To be just he was probably applying that much-abused word only to a vitamine hypothesis in the etiology of a particular disease. It was here, according to him, a "stunt," succeeding other stunts which had failed. Hopkins felt at the time, however, perhaps wrongly, that the implication was more general. Now, whether deficiency diseases are many or few, and even if it were ultimately shown that in the strictest sense there were none, the conception of vitamines is no stunt. It is based upon experiments as conclusive and as carefully controlled as any in biological science.

Referring to scurvy, the speaker pointed out that if there was one clinical condition in which the influence of deficiency seemed obvious, direct, and but little complicated, it certainly was scurvy. The manifestations of scurvy seemed to him to provide a bridge between the unequivocal results of experiments and the conditions more complicated and more difficult of interpretation which must be admitted to exist in some other cases. For surely the evidence that scurvy is a deficiency disease in the strictest sense seemed to be well-nigh unequivocal. The historic certainty that it was intimately related to diet took on a more definte form when the general idea of accessory food factors arose. This extended the conception of specific functions in nutrition, functions which were independent of energy supply. It brought the antiscorbutic factor into a class. Experiment, which had always the advantage over clinical observation in introducing quantitative methods and permitting of controls had certainly strengthened the evidence. Moreover, evidence for the deficiency hypothesis had, in the case of scurvy, accumulated of late from the laboratory, from the ward, and from the camp. Some might still look to infection as, at any rate, a secondary cause, but he could not, as he read the evidence, see any reason for this, except an obsession that some sort of positive factor must be called into account for every disease. Whether or not there were secondary factors in the etiology of the disease, there was, of course, no doubt about the prime importance of the food factor in treatment. Until laboratory investigations were undertaken, there were no satisfactory measure of the relative richness of various foods in the antiscorbutic substance. The recent qualitative studies at the Lister Institute had yielded results of extraordinary importance in this respect, and would put the therapeutics of scurvy upon a really scientfic basis.

As for rickets, the disease concerning the origin of which there has been and is a wide divergence of opinion, Hopkins expressed himself as remaining a firm believer in the influence of a specific diet deficiency, at least in experimental rickets as displayed in dogs, because in Dr. and Mrs. Mellanby's experiments he had seen carefully controlled observations showing unequivocal results. With regard to the clinical experiments of Drs. Hess and Unger, which seemed to show that deficiency in the fat-soluble vitamine had little to do with rickets, Hopkins trusted that he had read the accounts of these experiments without bias, but he felt that they failed to set the question at rest. That more than one factor was concerned in the causation of rickets seemed sure, but the relative importance of the different factors remained to be determined. Miss Hariette Chick, who has been doing work and making observations among the underfed young children of Vienna, expressed some of the ideas suggested by her experience. She drew attention to the fact that the absence of one or other of the accessory food factors might make the difference between health and disease. Regarding the food value of apples, or perhaps the antiscorbutic value of apples, she stated that lemon juice was found to be five times more valuable than apple juice. Dr. D. Dayell, a woman physician who also had been in Vienna recently, described some of the conditions among the child population there. There was, she said, no child of nine months which could be considered normal in that famine-stricken city. At the age of four months they began to show signs of malnutrition, and then feeding the nursing mother on butter had a wonderful effect on the child. When the mother was given 20 grams of cod liver oil daily the milk improved in quality, but not in quantity. The child also received 5 grams of cod liver oil daily, and grew rapidly. The enormously nutritive effect of a diet which contained fat soluble vitamine was demonstrated in the majority of cases. Butter was a sheet anchor of treatment, all of which is evidence to show that rickets is due to dietetic causes. The remarkable effect of intensive fat and cod liver oil treatment was strikingly shown in the case of a twin brother and sister. The girl came into the hands of Dr. Dayell and her colleagues when 5 months old, but the boy remained under the same dietetic conditions as before. In a few months, while the boy was still an ill nourished, miserable specimen of childhood, the girl, who had been given plenty of fat, had developed into a normal, well nourished baby.

Lieutenant-Colonel McCarnson, I.M.S., spoke next, and among the many interesting and instructive data he gave was the information that his experiments on monkeys seemed to prove that the late Dr. Charles Mercier was correct in his contention that improper diet tends to affect injuriously the mental powers, for these experiments showed that when young monkeys were deprived of their proper food their brains ceased to develop. Their brains increased or decreased in accordance with the kind of food they were given.

Dr. Alfred Hess, speaking of milk, said that milk pasteurized by simple heating did not lose its nutritive effects to the extent that commercially pasteurized milk did. He also said that dried milk, when properly dried, retained its nutritive properties. Scurvy had been cured by dried milk which had been kept for some months. Proper preparation was essential. The antiscorbutic vitamine was peculiarly susceptible to heat, and this milk must be prepared on scientific lines. Mistakes were often made in the diagnosis of scurvy and rickets. Lack of fat-soluble vitamine did not play the important part in the causation of rickets that lack of antiscorbutic vitamine did in scurvy, and yet he believed that rickets was largely a dietetic deficiency disease.

Dr. G. Still said that in the elucidation of the origin of what were known as deficiency diseases, more progress would be made if there were greater cooperation between the clinician and the laboratory worker. He suggested that inheritance might be a factor in the causation of rickets and the personal equation must be considered. According to Still baked potato is the best antiscorbutic, considerably more effective than orange juice.

Dr. Leonard Williams said that all diseases had their origin in dietetic deficiency. Civilized people lived on an artificial diet, on cooked food. Uncooked food contained the vitamine element which was comparatively absent from cooked food. He said there were two chief reasons why people ate cooked food; one was that it was more palatable, and the other reason was the fear of microbes. He pointed out that this fear was illusory, and in fact bacteria were our best friends. He advised an intensive vitamine treatment by means of a diet of uncooked food, which was better than drugs.

Dr. C. Muthu said that he quite agreed with Dr. Leonard Williams that all diseases could be attributed more or less to some food deficiency. Experiments on fresh and stale vegetables and fruit, conducted at the Mendifs Hills Sanatorium with the aid of a galvanometer, showed that the life of animal or vegetable protoplasm depended upon its electromotive force, and that the fresher the vegetables and fruits the more intact were their electrical properties and the vitamine and food accessories, and that the staler and more cooked the food the greater its electrical diffusion and destruction of its enzyme properties. The nutritive value of a food seemed to depend upon its freshness or raw state, which insured healthy and active enzyme and vitamine conditions and easy digestion and assimilation. Civilization meant stale and cooked food, frozen

and canned food, artificial and adulterated foods, in all of which there was a deficiency and destruction of enzyme properties and food accessories which laid the foundation for pathological changes and diseased conditions. The food question was therefore of vital importance to the health of a nation. Tuberculosis was a deficiency disease, and the great war had proved that famine and starvation led to chronic malnutrition, rickets, and tuberculosis. A disease like tuberculosis was an expression of hunger—hunger for a fuller and more natural life—for more fresh air and fresh food, and more congenial surroundings. Let us improve the well-being of a nation and we shall go a long way in the direction of eradicating deficiency diseases.

Annual Temperance Breakfast.—On the invitation of the National Temperance League, Sir Clifford Allbutt and many members of the association breakfasted in the hall of the University Union Society. Sir G. Sims Woodhead, Professor of Pathology at Cambridge University, spoke of the benefits of abstinence from the general standpoint. From what one had heard, he said, men who were not total abstainers had come back from America enthusiastic in the belief that by her dry policy she had taken a step which was going to place her very far forward in the international race. Mr. McAdam Eccles, surgeon at St. Bartholomew's Hospital, London, said the public looked to the medical profession to give no uncertain sound regarding the value to health or otherwise of alcohol. If it was physiologically unsound they should tell the scientific truth and pave the way for the will of the nation. Sir Clifford Allbutt said that alcohol, when taken intemperately during the war, was distinctly on the side of inefficiency. Alcohol was a disadvantage to mountaineering, as he had experienced, and he had little doubt that that applied to the whole work of life. During twenty of the hardest years of his life in Leeds he had been a total abstainer, and was very much the better for it.

Cancer Research.—In the section of pathology, Dr. J. H. Murray, Director of the Imperial Cancer Research Fund, dealt with the present position of cancer research. Dr. Leach of Liverpool, who took part in the discussion, referred to the hope expressed by surgeons that there might be an early diagnosis of the disease. He felt that that was a vain hope because sufferers would not see a surgeon until they had some definite symptoms of the disease. By the gradual accumulation of post mortem anatomical investigation they were able to a fair degree to see now the trend of cancer. He thought the results had been very promising. If they considered cancer of the breast, uterus, and rectum at the present time treated by operation, something between 40 and 50 per cent. of the patients remained free of it for a period of about five years. They could not do anything like that 15 years ago, and he would not be surprised if 15 years hence that number were very considerably increased.

Venereal Disease in Women and Children.—In the section of venereal diseases, the disease in women and children was dealt with respectively by Dr. Morna Rawlins and Dr. Leonard Findlay. Many of the speakers drew attention to the fact that there was still a good deal of ignorance respecting the treatment of venereal disease. Sir James Galloway pointed out that the intensive treatment of syphilis sometimes brought about other diseases. Dr. Marion Mackenzie, who has done much work at the prenatal stage, urged that women who were infected with syphilis should be instructed how not to have children. The meeting was almost unanimous in the view that venereal disease should be made notifiable. Dr. Alcock expressed the opinion that that would be a very difficult matter in the smaller towns, where people were all known to one another. In some small areas, however, notification might be made to the county authorities or even to London headquarters.

Dr. E. W. Turner of London thought that there should be compulsory treatment for infected persons, but admitted that it was a matter on which public opinion might take years to come to this way of thinking.

Voluntary Hospitals and State Supported Patients.—One of the most interesting meetings of the week was that of practitioners, who gave their services free in voluntary hospitals to consider the position which had arisen through hospitals treating State supported patients. The meeting, which was largely attended, was presided over by Sir Cuthbert Wallace of St. Thomas's Hospital. Professor Bolan of Newcastle-on-Tyne said that the representative body had seriously considered the situation and had accepted the view that for all work undertaken at voluntary hospitals for soldiers and sailors, whether discharged or not, for any disease or injury connected with the war, the medical staff should be adequately remunerated. They ought to make their position clear in view of the prospect that State-aided work in hospitals was going to be greatly extended in the immediate future. It was hoped that before long insured persons would be able to receive institutional benefits; that would revolutionize the basis on which they had been accustomed to work.

Mr. McAdam Eccles of London indorsed the view put forward that if they declined to accept adequate pay it would mean State exploitation of the profession. Dr. L. Stephens said he believed the Labor Party would support them in a reasonable demand. When he told labor men that some doctors worked thirteen and one-half days out of a year for nothing they said, "You must be mugs to do it."

Eventually a resolution was passed approving the action of the hospital committee of the association with regard to the remuneration of the staffs of the voluntary hospitals for work done on behalf of State aided patients and promising support in bringing the subject before the notice of the governing bodies of the voluntary hospitals of the country.

Section of Medical Sociology.—Sir George Newman, Chief Medical Adviser to the Ministry of Health, opened the meeting by discussing the State and the future of medical practice. He said that whatever else the profession gave up, they must not part with the particular genius of individualism. People talked of the nationalization of the medical profession. It simply could not be done, and Sir George promised that so far as he was concerned as an instrument and a servant in the matter, he would do his best to see that it was never attempted. He was fed up with stunts here, stunts there, and stunts somewhere else which had no possible relation one to another. The profession feared the imposition of some cast-iron system, some form of so-called nationalization, the institution of a whole-time civil service. What we seemed to need in the abstract was a single unit of health government with subcommittees for necessary purposes. There was also needed an extension and coordination of medical provision and an adequate method of medical education. The claims of the State on the profession had greatly increased, owing to the advance of medicine and its manifold application. A new and closer relationship between them was inevitable. It could be made of profit to the public interest only by good understanding. The State should never take out of the hands of the general practitioner the patient whom he was willing and competent to handle on reasonable terms. The speaker pointed out that the medical practitioner, apart from the fact that he might be called upon to undertake official duties in the public service, was liable under statute in the following respects: (1) He must certify births and death and notify all births within thirty-six hours; he must notify cases of infectious disease, of industrial poisoning and of verminous children. He must also be ready to vaccinate and to certify the removal of infectious cases to hospital. (2) He may be called upon to inspect and certify for house disinfection and be prepared to issue certificates for the removal and burial of dead bodies. (3) He may be required to inspect and condemn in regard to nuisances and insanitary house property; or inquire into unhealthy or insanitary areas. (4) He must know something of the ill effect upon health of dangerous or offensive trades or of unsound food. (5) He must be competent to diagnose all forms of mental disease. (6) He must be available to respond to the requirements of the local sanitary authority for the provision of medical assistance and treatment of the poorer inhabitants of the district in which he lives. (7) He is liable to a series of duties in regard to workmen's compensation and pension claims. (8) He may be called in by a midwife to assist in cases of emergency. (9) The local education authorities may avail themselves of his services in connection with the treatment of children and young persons.

Sir Wilmot Herringham, speaking from the consultant's standpoint, argued that there would continue to be room for the consultant. There was the sage reflection that two heads were better than one to satisfy the anxieties of the patient and his friends. At the present time he added there were two classes who obtained the best treatment to be found in the country, the rich and the poor. The former could afford to pay large sums and to have every requisite and comfort during illness, and the latter were treated in hospitals and were probably the better served of the two. The middle classes came off very badly. Sir Wilmot declared that he should like everything that was so admirably organized for the poor to be placed at the disposal of the deserving middle class. Mr. E. W. Morris, house governor of the London Hospital, situated in the heart of the poorest district of London, and which is in dire financial straits, dwelt on the hospital outlook. In his opinion, considering the enormously increased cost of running the voluntary hospitals, the time had come when patients should as a matter of duty contribute to the cost of their treatment. He would take the plunge. He firmly believed that the day of partly staffing voluntary and teaching hospitals had gone. The time had come for the provision of a properly remunerated and whole-time clinical staff.

Mr. D. I. Jenkins, secretary of the Labor Party Advisory Committee of Health, said that until the passage of the Insurance Act it was extremely difficult for the average working man to obtain any kind of medical attendance. He went on to say that the institutional treatment of tuberculosis as now practised was the most colossal failure that the country had ever attempted. Better far to put these patients into a lethal chamber than to hold out fake hopes of saving them. They of the Labor Party were not asking to spoon feed the workers. The medical profession should educate them. Certain work caused certain diseases, and they believed those diseases could be avoided if research was adequate. They did not ask the profession to accept the proposal of full-time State medical service without giving the profession a measure of interest and control in it, and they were quite prepared to pay for it. Dr. Macdonal of York estimated that a State medical service would cost forty million pounds sterling a year. Sir Wilmot Herringham said Mr. Jenkins, who represented the Labor Party, was the only advocate present of a State service.

ASSOCIATION OF AMERICAN PHYSICIANS.

Thirty-Fifth Annual Meeting Held in Atlantic City, May 4 and 5, 1920.

DR. HERMANN M. BIGGS, PRESIDENT, IN THE CHAIR.

First Day—Tuesday, May 4.

President's Address.—Dr. HERMANN M. BIGGS of New York, in addressing the Association, said the first part of the President's duty was a sad one, namely, to record the losses by death which the Society had sustained during the past year. This time the names of Sir William Osler and Dr. Abraham Jacobi, men of untiring energy and striking intellect, were upon the list, as also those of Dr. H. C. Wood, a noted teacher, and Dr. E. E. Southard, whose name had been scheduled to appear upon the present program.

It also devolved upon the President to present to the Association some topic dealing with the general or educational aspects of medicine. Dr. Biggs therefore chose as his subject the status of medical practice in rural communities. There was noticeable a great lack of hospital and laboratory facilities and of high class medical men, which condition had become so acute that some solution of the problem must be forthcoming. Much had been heard of a widespread demand for some form of health insurance, modeled upon the German or the British plan. Such legislation would influence medical practice for the worse and not for the better. Another inevitable tendency was for health authorities to enlarge the scope of their work, and although some physicians thought this undesirable, government aid to the practice of medicine seemed bound to take this form. In the country as a whole there existed an actual shortage of physicians, and men tended to concentrate in the larger cities. Higher requirements as to entry into medical schools had brought about a diminution of 50 per cent in medical students, and the relatively inadequate rewards offered to the profession compared with other pursuits, still further depleted the ranks. The supply of nurses also was growing more and more inadequate, though the demand was greater. Nursing schools found it impossible to obtain enough nurses, and the absence of domestic servants in the rural districts added to the problem. It therefore became more necessary that patients should be admitted to well-equipped hospitals. Such hospitals, however, were not accessible to country people and country hospitals were small and poorly equipped. The increase of cost of maintenance of hospitals was making increase in their number impossible. There was also a shortage of public health workers, owing to inadequate salaries paid to health experts along all lines. In hospitals it was so difficult to obtain internes that a shortage of 15 to 45 per cent was evident on all sides; many State institutions for the insane had become merely custodial in nature, on account of shortage of medical attendance. When one came to inquire as to the status of physicians in rural communities it was found that in one typical community counting on 54 physicians, all of them had averaged 28 years in practice. The drift from the farms to the cities, on account of lack of educational facilities in the country, was another phase of the situation. To remedy this increasing evil the government must adopt some scheme by which the rewards of medical practice could be made more substantial and by which rural communities could be aided to provide facilities, the richer cities contributing their share towards this purpose by means of appropriations. Recently, Dr. Biggs said, he had introduced a bill in the New York legislature. for the establishment of rural health centers to be supported partly by taxation of the district, partly by payment by the patients, and partly by State aid. Such centers would include hospitals properly equipped and divided into pavilions for the specialties, provided with laboratories, with a public health and nursing service, and with medical and nursing attendance for the schools. There should also be periodical clinics where local practitioners could be assisted by consultation with specialists in regard to the diagnosis of obscure cases of illness. There should be a full-time health officer and the building would be a center for all public health activities of the district. This plan would be expensive, but all scientific medical care was expensive. This bill was not passed, because sufficient time had not been allowed for its discussion, but it was likely to receive favorable consideration. Representatives of almost every class were in favor of it. By this means medical practice would be made more attractive and lucrative in the rural districts. The only bodies that had given their opposition to the plan were the New York County Medical Society, the King's County Homeopathic Society, and the Christian Scientists.

Refinement in Methods of Auscultation of the Lungs by Electrical Means.—Drs. W. CHARLES WHITE and L. O. GRONDAHL of Pittsburgh made this presentation. Examination of the physical condition of the normal and the abnormal lung, in regard to their readiness of sound-conduction, was made. This work included study of (1) sound producers; (2) sound conductors; (3) sound receivers. The first and third could be modified; the second not. The sound producers included the inspiratory and expiratory mechanism of the body; the voice, whispered and spoken; percussion; certain explosive sounds such as râles in the lungs; friction sounds. The sound recorder has hitherto been the human ear. The conductors were the body tissues; the air confined in columns in the lungs or in the stethoscope. The objection to the human ear as a sound recorder was its fatigability, the tiring of the ear representing an economic loss in the study. Thus a study was attempted with the idea of recording sound in some more invariable and permanent fashion. Working in a pneumophysical laboratory and reproducing the records made, on charts, fairly constant results were obtained. It was found that percussion was fairly constant as a sound producer and that, as the volume of the lung increased from the apex down-

ward, the volume of sound increased. Intermediate sounds, those produced between the bell of the stethoscope and the interior of the lung, were difficult to understand and interpret. A wide difference between tracheal, bronchial, and vesicular murmurs was shown. The difference between colon, liver, heart, and lung percussion was noted, each having its characteristic record.

Dr. L. O. GRONDAHL, who explained the mechanism used, said that the apparatus consisted of a telephone transformer and amplifier used in conjunction with a string galvanometer. The objection to the amplifier was that it mechanically amplified all sounds alike and thus one could get sounds that one did not want to hear amplified. The instrument as used would give a permanent record, the vibrations of the strong corresponding to the variations in the pressure curve, the intensity of the sound being registered by the amplitude of swing of the string; the pitch, by the frequency of vibrations, and the quality of the sounds being marked by the character and shape of the curve. A tone of pure sound would give a pure sound wave. Complicated breath sounds did not give a pure sound wave. It was easy to see by the records the difference between sounds of different kinds, as, for instance, between resonant lung and dull lung. The great difficulty was in eliminating extraneous sounds. In the stethoscope one heard the sound one wanted to hear, in this instrument everything was equally presented. The problem was to distinguish sounds of different frequency. With the telephonic receiver connected with an alternator one could pick out a sound of any frequency required.

Dr. H. A. CHRISTIAN of Boston, said that at the meeting of the National Research Council an endeavor had been made to bring together a group of biologists interested in the physical side of their work and a group of physicists interested in the biological side of their study, so that the fundamental qualities of biological material, which in the last analysis were probably physical, could be studied from this combined point of view. Hitherto there had been a great gap between these two branches. The working committee consisted of Dr. Williams of New York, Professor Ives, Dr. Bovee of Boston, and Professor Lilly of Clark University.

Dr. FRANCIS WILLIAMS of Boston asked if, when the amplifier was used, was there any difficulty from external noises, as for instance from the passing of street cars or automobiles. He wondered if, with the use of the filters spoken of, it would be possible to exclude undesirable noises.

Dr. GRONDAHL, in closing, said that as soon as one began to use the amplifier, one's troubles increased. So far, in regard to external noises, exclusive of the noises in the stethoscope, there had been no difficulty. The motors, when placed too near the instrument, had been a disturbing factor, but these were easily placed at a convenient distance.

Some Observations on Chronic Arthritis.—Dr. GEORGE DRAPER of New York read this paper which was a preliminary communication. In studies made on meningitis in the army it was found that persons infected, were all of a type that presented a certain similarity in external bodily appearance. Following this idea of external characteristics being in some way related to liability to certain diseases, a study was undertaken of persons presenting the arthritic complex. This was apt to appear most frequently in women, and was associated with menstrual irregularities and with pregnancy. The pulmonary arthropathies were related to chronic bronchitis and asthma. The patients often presented skeletal characteristics suggesting acromegaly. The blood picture was found to be typical. Nervous fatigue, hives and urticaria were included in this syndrome. Chronic arthritis represented profound constitutional disturbance, probably related to endocrine pathology, involving sometimes the thyroid, but more often the pituitary. The effects of bee-sting therapy were reported, not so much because of therapeutic properties, but because they emphasized the relationship of protein shock as expressed by hives and angioneurotic edema, to the group of diseases in which chronic arthritis and asthma figured so prominently.

Dr. EMANUEL LIBMAN of New York said he believed that there were very important points in Dr. Draper's paper. He thought, personally, that infection attacked the joints because of a previous condition of the patient, the ductless glands having been the cause of disturbed metabolism. Dr. Draper had said that he found arthritis was associated with a sort of subthyroid condition. This had been previously discussed under diatheses, but one had also to explain those metabolic disturbances. Certain physicians thought of certain diseases in patients of a certain type. Dr. Delafield used to say, in regard to dysentery, that he could look at a man in New York and tell what was the matter with him although he might not be able to do that in Chicago or in Manila. This question no doubt had a bearing on drug idiosyncrasies. One could look at an individual and say what idiosyncrasy he would present to a certain drug.

Dr. R. ROBINSON said he was very much interested in hearing Dr. Draper speak of a patient's reaction to bee stings. During a trip in the mountains of Pennsylvania one of the party had been stung by a hornet and five minutes after developed intense edema of the face, difficulty of vision, urticaria, and general weakness. After half an hour, vision improved. There was a very intense urticaria all over the body, and rapid and weak pulse. This may have been some form of anaphylactic reaction.

Dr. HENRY A. CHRISTIAN of Boston said that Dr. Walter had made charts showing the heredity in cases of asthma, and from his studies had come to the conclusion that the factor that was hereditary was the protein sensitization. There was no inheritance of sensitization to any particular form of protein; many of the idividuals had no symptoms and no disease, except sensitiveness to one or another protein. Many others had asthma; arthritis was common. No particular disease might be inherited but the general principles of inheritance of sensitiveness seemed to correspond to the Mendelian law.

Dr. KOPLIK of New York said, in regard to children, that a large number of them suffered from asthma, and many gave reactions to sugar in the form of eczema. An outbreak of eczema would relieve the asthma. Often one could trace in the parents of these chlidren a sensitization. They were affected with "acidity" and showed local spots of eczema. Some of the children complained of joint pains; these did not have asthma, so that it seemed as if this reaction was selective and attacked certain children in certain organs.

Dr. S. SOLIS-COHEN of Philadelphia said that this was all part of a much larger question. There was a peculiar inherited familial liability to certain disturbances of the autonomic nervous system and the endocrine glands which manifested itself in different groups, in different families and in different members of the same family, and in one individual at different periods of time, under varying conditions. The difference in aspect depended upon two additional factors: One was the difference in the special exciting cause and the other the conditions determined in the individual himself. These cases should be analyzed from three standpoints: (1) hereditary liability; (2) particular exciting cause; (3) particular local determinant. Osler, in his studies in 1887, pointed out the whole relationship of these disturbances in sensitive persons. He discussed horse asthma, hay fever, pseudo-appendicitis, angiospasm, etc., in a group of persons who had a tendency to metabolic disturbances and presented insufficient carbohydrate and fat metabolism. Persons who showed glycosuria and diabetes seemed to have a distinct resistance to tuberculosis and to carcinoma. On the other hand individuals suffering from carcinoma or tuberculosis escaped these disturbances. Dr. Cohen said he could not pretend to give the explanation, but the facts were very noticeable. This discussion took in only a corner of a very large field.

Dr. LEWELLYS F. BARKER of Baltimore said he thought Dr. Draper had made a very laudable attempt to correlate disposition to infection and the effects of infection. In discussing constitutional make-up one should ask how far did constitutional peculiarities make the individual liable to infection, and how far did endocrine disturbance modify the make-up after

infection had taken place. In regard to the arthritic diatheses, there was evidently a predisposition to arthritic infection. That the endocrine glands had much to do with external habit was established, but one should study the endocrine make-up preceding the infection. Arthritis often led to endocrine disturbance. The thyroid was upset by infection and responded by hyperplasia. Infection in the lungs might be through hypophyseal disturbance. It was hard to determine how much disturbance preceded infection and how much was secondary to it.

Dr. DRAPER in closing said that this was a very complex problem. Dr. Robinson had spoken of the edema of the face following a hornet's sting. In the literature, sudden deaths had been recorded from bee stings about the head, although such persons had been previously stung about other parts of the body without bad result. This discussion had automatically turned into one on asthma. Dr. Koplik had mentioned the alternation between eczema and asthma. There was evidently a pituitary influence in the asthmatic; and the skin disturbance might possibly be adrenal in origin. Dr. Barker had summarized the whole situation so far as infection was concerned.

Effect on Blood Pressure and Blood Nitrogen of the Ingestion of Large Amounts of Fluid.—Dr. JOSEPH L. MILLER of Chicago presented this communication. Experiments were conducted by giving large amounts of fluid to see the effect obtained on the non-protein nitrogen. The water was introduced by the Rehfuss tube, 2½ liters every three hours, till hydremia was produced, and the blood nitrogen was then determined. The urine output was measured and the patient was weighed before and after each period of the water intake. The patients tested had high blood pressure and a steady rise was observed. In one man the blood pressure rose form 160 to 280 mm., and the weight from 124 to 142 lbs. The next day the weight and blood pressure fell, but he complained of dyspnea and distress. Water administered to the same patient at night caused the blood pressure to rise from 170 to 260 mm. and the weight to rise 9 lbs. The blood urea was 34 mg. urea nitrogen per 100 cc. blood before the test, and after the test slightly more. There was a 50 per cent. reduction in uric acid, the creatinine was unchanged. In the other patients (3) tested, the results were comparable. The conclusions were that ingestion of large amounts of fluid had no effect on the urea nitrogen, though there was reduction of the uric acid. When large amounts of water were passed (as in one patient) the blood pressure was not affected.

Dr. HARLOW BROOKS of New York asked if that was distilled water, or ordinary tap water.

Dr. ROWNTREE of Minneapolis asked if the reader of the paper had made any studies of nitrogen excretion. He would particularly like to know about the uric acid disturbance. Did any of the patients develop edema?

Dr. AUSTIN said that in normal persons the urea excretion was increased by increasing the intake of water at the rate of 3 to 5 liters a day, but beyond that point increasing the urinary output did not increase the urea.

Dr. F. M. ALLEN of New York said that in regard to drinking of large amounts of water, there were types of cases where the tension gould go up with drinking large amounts of water. These were the normal tension cases. In the hypertension cases where the water was eliminated rapidly the tension did not increase. If one gave these patients salt the tension would go up and if a patient with a pressure of 200 got salt then there would be fireworks. In one type of normal pressure there was a tremendous lag of excretion and the blood would show a volumetric increase but there was no rise of pressure because the patient got edema. The blood showed great reduction in soluble substances and nitrogenous constitutents. When excretion was increased the distilled water swept out some of the chloride and there was a fall in blood pressure.

Dr. E. P. JOSLIN of Boston said that in considering the elimination of nitrogen one should bear in mind the total metabolism of the individual. In the usual quantity of liquid drunk the metabolism was little changed; with a large quantity metabolism was affected. Unless one remembered this metabolic change one might not account correctly for the nitrogen excretion.

Dr. LOEVENHART asked if the rise in pulse pressure was due to rise in pulse rate. Was there an increase of cardiac output per beat?

Dr. H. A. CHRISTIAN of Boston asked if there was a diuretic or non-diuretic effect

Dr. H. O. MOSENTHAL of New York said that in considering this problem one conclusion would not apply to all cases for the reason that a diuretic effect produced by water would vary very greatly. Water ingested in large quantities instead of causing diuresis might result in oliguria; at times it might produce diminished water content of the body. The effects on blood pressure might be interpreted from two different points of view: (1) a definite nervous effect on the individual; (2) the tension of the nervous system might produce rise in blood pressure.

Dr. MILLER, in closing, said that none of the patients showed any edema. There was a definite diuresis. One patient passed 3,700 c.c. between 9 A.M. and 6 P.M.

Acute Psychoses in Diseases of the Heart.—Dr. DAVID RIESMAN of Philadelphia read this paper. He said that acute mental disturbances sometimes appeared during the course of heart disease with such startling suddenness as to disconcert the attending physician and to prove a severe shock to the patient's family. These disturbances varied, being apt to take the form of hallucinations, of confusional states, of acute mania, or of delusions, especially delusions of persecutions. Often the patient would state that he heard the sound of bells, or smelt some unusual odor, or occasionally the face of a man or a woman would be seen, which appeared and vanished. It should be explained to the patient that such illusions were caused by anemia of the brain. In acute pericarditis acute mania sometimes presented itself, and it would be well in all sudden cases of acute mania to examine for pericarditis. With lesions of the aortic valve delusions of persecution were sometimes noted. The relation of these psychoses to the heart condition might be accidental, but frequently the heart disease was the causative agent. Renal insufficiency, acidosis, and drug intoxication might be factors. Digitalis had at times been held responsible, but, considering the enormous frequency with which this drug was administered, it was unlikely that it was the cause of acute mania or other acute psychoses, seeing that the latter were rather rare.

Dr. GEORGE BLUMER of New Haven said that many of these cases were of syphilitic origin, especially those disturbances accompanying aortic lesions.

Dr. HERRICK of Chicago said that these disturbances developed largely as a result of the circulatory inhibition in the brain, and there was often very distinct evidence of toxemia. The disturbance of metabolism resulted in an accumulation of toxic material in the blood. Occasionally toxic material was introduced, for example, alcohol or digitalis, or occasionally bromides. Morphine, hyocine, and bromine were often given with too free a hand. One other fact had been noted, namely, the hopefulness of some cardiac patients; some it was true, were irritable and nervous, but in some cases their hopefulness was comparable to that seen in acute phthisis. Dr. Blumer's point was well taken; aortic disease was often syphilitic, but it did not often have mental symptoms.

Rebreathing and Ergometer Determinations as a Method of Estimating Cardiac Efficiency.—Drs. ALFRED STENGEL, C. C. WOLFRETH and L. JONAS of Philadelphia presented this paper, read by Dr. Stengel. Studies were made, using the rebreathing apparatus of Henderson, thus producing anoxemia. It was endeavored to test cardiac efficiency by this method. According to Henderson compensation for exertion was brought about by increase in respiratory work and increase in circulation. Haldane, however, did not think that these compensated for lack of oxygen. Thus opinions were conflicting. In the studies undertaken a bicycle ergometer with 6,000 foot pounds of work was used, with a Douglas bag for respiration. Patients with pneumonoconiosis and with valvular lesions were studied. On the whole the results on anoxemia did not furnish the valuable data hoped for.

Dr. MCKERNON said that these oxygen want experiments had to be studied with very great care; recently one well-known physiologist died as the result of oxygen want experiments.

Dr. ROWNTREE of Minneapolis said that in the army aviators were classified according to the elevation they could stand, 18, 15, or 8 thousand feet; the latter corresponded to the type Dr. Stengel showed on his last two charts. The ability to stand anoxemia had a relation to cardiac disease. One must consider myocardial involvement. There were a number of normal individuals who gave various reactions and the tests should be made with great care. They were very important from a psychological point of view. Some of the patients presented psychological phenomena and symptoms resembling an attack of petit mal, although no evidence of circulatory collapse.

Dr. STENGEL said this was a valuable method for studying anoxemia, but whether one could pick out the circulatory reactions was doubtful. Some cases with marked myocardial lesions responded the same way as did the controls, so that the cases could not be diagnosed by this means. One patient showed a momentary loss of consciousness.

Effects on Cats of Digitalis Lutea and Digitalis Thapsi, as Noted During Intravenous Injection, with Simultaneous Electrocardiographic Tracings.—Dr. R. E. MORRIS and Dr. S. MARX WHITE, presented this paper, read by Dr. White. Three methods of estimating digitalis dosage were in use: the frog method, the guinea-pig method, and the cat method of Hatcher. In these studies the latter was used. There was a wide variation in the percentages of the lethal dose. With varying doses changes in the waves of the electrocardiograph in the ventricular complex, and in the various degrees of block in the bundle branches were noted. These changes were comparable with those produced by other species of digitalis. The changes noted in individual variations in the effects might have some bearing on studies of absorption by the gastrointestinal tract.

Dr. ROBINSON said that this series was very similar to that published by Joslin and himself but that he thought the lethal effects were obtained a little earlier in their work, than the figures belonging to this preparation of digitalis. The method was of value as one could determine the quantitative action in animals as compared with that in man. About 25 per cent of the lethal dose would give the same effect as one obtained in patients. This new form of the drug might be more readily obtained in America, than the older form.

Dr. WILDER TILESTON of New Haven asked whether this drug had been used sufficiently in man to say whether it was as efficacious as the other, and without injurious effects.

Dr. WHITE, in closing, said that he did not think the results, according to their tables, were very closely comparable, but there was no difference apparently in the lethal dose. As regards clinical administration, thapsi was much more closely related to purpurea. Lutea had been given to 40 patients and there was a lessened amount of nausea and vomiting. The effects in man were equal to those of purpurea. The great accuracy of this study might have had some influence, as the speaker said that purpurea had never been given under such scientifically accurate measurements.

The Total Metabolism in Diabetes.—Dr. E. P. JOSLIN of Boston read this paper. Metabolism estimations should be made in regard to height, weight, age and sex. In woman the metabolism was 6 per cent. lower than in man, and with each year of life metabolism decreased by 7 calories. In diabetes Benedict had noted metabolism both above and below the normal. Studies made before 1914 showed different results to those made after that time when Dr. Allen had started his metabolism experiments. The newer methods showed increase of life due to wiping out of diabetic accidents. Before 1914 acidosis was a factor. There was no evidence to show that acidosis increased metabolism. Levulose increased metabolism 17 per cent. Metabolism could not be judged by pulse alone, although there was a relationship and pulse readings should be carefully made. Where the metabolism was 660 calories per sq. meter of body surface, the pulse would be 60. Studies must be made also as to sugar and non-protein nitrogen in the blood.

Dr. F. M. ALLEN of New York said that diabetes was a disorder in which the total metabolism was involved. Over-feeding the patient raised his metabolism. The patient must accept his lowered metabolism, then he could live indefinitely, one must not try and drive his renal function.

Chemical Studies on Edema.—Drs. FREDERICK M. ALLEN and J. W. SHERRILL of New York presented this paper. Analyses for urea, creatinine, chlorides, bicarbonates, sugar, and sometimes acetone were made of over 40 exudates from various parts of the body in various conditions, chiefly nephritic edema and the bicarbonate edema of diabetics. No distinctive differences were found between the cases. The chief general characteristic was that the concentration of the inorganic constituents was higher in the exudate than in the blood plasma, so that the fluid accumulation seemed to correspond to osmotic laws, irrespective of the clinical conditions producing it. The relations of the organic substances were variable, but the distribution of all of them between blood and exudate was always unequal. On feeding various substances, the concentration of all constituents in the blood was much more easily and quickly altered than that in the exudate. Lowering the plasma bicarbonate by exercise or forced breathing did not increase the bicarbonate in edema fluid. The fullest study was made upon a young man with heavy albuminuria and casts, good renal function as tested for urea, chlorides, and phenolsulphonephthalein, and marked edema which resisted all dietetic restrictions. The chemical relations between blood and edema fluid resembled those found in cases which responded readily to diet, and also the results of feeding sugar, protein, sodium chloride, sodium bicarbonate, and hydrochloric acid were similar. There was a very marked delay in the excretion of water, with great dilution of the blood and increase of edema; but the edema still persisted under a dry diet which raised the hemoglobin and red cell count above normal. As the edema seemed unexplainable by renal retention, chemical differences, or permeability of membranes, it could be accounted for hypothetically only by mechanical factors, such as abnormalities in the capillary circulation.

Blood Analyses in Some Ophthalmic Conditions.—Drs. J. W. SHERRILL and FREDERICK M. ALLEN of New York read this paper. Dr. Allen said there was a certain notorious frequency of association of certain ocular disorders with various metabolic disorders, especially of cataract and retinitis with diabetes, nephritis, and hypertension. The therapeutic relationship proved that the metabolic trouble was either the primary or the exciting cause of the eye trouble. Thus, diabetic cataract was prevented by proper dietary control of the diabetes, though such treatment did not cure the lens changes after they had begun. Diabetic retinitis could both be prevented by dietetic treatment and arrested after it had begun. Much was also accomplished by diet for the eye troubles of nephritis and high blood pressure. An investigation was therefore naturally suggested into the metabolic state in various ophthalmic disorders in which the etiology had seemed obscure. Reference was made first to 7 cases of retinitis occurring as a prominent feature in metabolic disorders (diabetes, nephritis, hypertension, separately or combined) under treatment in the writers' hospital. The retinal changes were in the form of hemorrhages and exudation, together with secondary optic atrophy in 2 cases. In all 7 cases the ocular and the general condition were severe and progressive. One patient with combined diabetes and nephritis was in the terminal stage and already blind. Two patients with nephritis and hypertension had low plasma chlorides to start with; their hypertension was benefited but not entirely overcome, and the same was true of their retinitis. In the other 4 cases (2 diabetic, 2 non-diabetic) the retinitis was arrested, even when the blood pressure was not brought fully to normal. Aside from the usual diet for diabetes, emphasis was laid upon salt-free diet as the effective therapy in all these cases. Another hospital patient had diabetes, high blood pressure, incipient cataracts, and severe progressive myopia. Diet and reduction of the blood pressure by salt privation had given such encouraging results in the eyes to date, that a metabolic examination and possible diet treatment were suggested in other cases of progressive myopia. Analyses of the blood for sugar, urea, and chlorides in 7 clinic patients with retinitis, 19 with

cataract, and 13 with miscellaneous disorders revealed altogether 7 cases of diabetes, but otherwise gave no constant results. Dietetic treatment was not attempted in these cases. Similar examinations in 36 cases of chronic simple glaucoma revealed 6 cases of diabetes. It was striking that the plasma chlorides were above 600 mgm. per 100 c.c. in 31 cases, and in the other 5 were 595, 594, 588, and 563 mgm. per 100 c.c. One of these patients had been taken into the hospital for trial of salt-free diet. His renal function tests, especially the urea index and the chloride threshold, had been found normal, and he had had no edema; nevertheless an abnormal tendency to chloride retention had been demonstrable. At first, with plasma chlorides 610 mgm. per 100 c.c., his introocular tension was R 45, L 43. After 3 to 4 weeks of salt-free diet the chlorides were reduced to 565 mgm. per 100 c.c., and the intraocular tension fell to R. 34, L. 32. A test to determine whether salt addition would raise the intraocular tension was still incomplete. The observations did not indicate that salt was a cause of glaucoma, and the fall of tension in the single case might be purely accidental; but there was a possibility that salt-privation might be to some extent beneficial in such cases. Two cases of retinitis of unknown origin, referred by oculists for metabolic examination, had proved especially interesting. These patients had normal blood pressure and normal response to real tests, except that the plasma chlorides and the chloride threshold were high. Salt-free diet was used in these cases with decided benefit. In 1 case the improvement was apparent only to the oculist, as the damage was too advanced for restoration of vision. In the other case the retinitis had halted and the vision had risen from 20/70 to 20/30. The study was still incomplete, but a conclusion was warranted that a considerable number of ocular disorders would call for metabolic examination and treatment. The principal or only "toxin" responsible for many cases of retinitis seemed to be common salt. The judgment in any individual case should be based upon accurate tests and not upon a general assumption. Also the diet was a matter requiring skill in both planning and preparation. The patient who was merely directed to avoid salt generally did not succeed in avoiding it to the necessary degree of thoroughness, and in many instances institutional care was necessary for success in the diet treatment.

Dr. ALLEN said he did not want to make people believe that chlorides were to be blamed for every kind of condition. In diabetes there was high blood sugar, iritis in the eye and a tendency to infection in all parts of the body, arteriosclerosis, gangrene, and various systematic disorders. One had to prevent the high blood sugar. Many of these patients got on with high blood sugar, and no complications. Also one might have high chlorides in the blood without complications. Still, there were disturbances with high chlorides and chlorides were the strongest osmotic agents; thus abnormal retention could cause many disorders, edema, arterial hypertension, and some skin disorders. One author attributed the convulsions of eclampsia to high chlorides. The nervous disorders of epilepsy and the psychoses with edemas in cardiac conditions might be phenomena of chloride retention. One should study salt retention to see what it did and what it did not do, and discard other influences.

Experiments with the Influenza Bacillus.—Dr. RUSSELL L. CECIL of New York City, made this presentation. He said that previous efforts to transmit influenza to man by inoculation with the influenza bacillus had been for the most part unsuccessful. These failures might have been due to one or more of several causes, namely, (1) Natural or acquired immunity on the part of the subject. (2) Insufficient dose of the culture. (3) Loss of virulence in the culture used. In the experiments reported by the author, six healthy volunteers were inoculated in the nose and throat with a strain of *B influenzæ* freshly isolated from a case of clinical influenza. Preliminary cultures showed that only one of the volunteers was a *B. influenzæ* carrier, and he denied ever having had the disease. Three out of the six volunteers gave a history of influenza during the epidemic of 1918; the other three denied having had influenza at any time, though they admitted frequent exposure. Two of the volunteers received the washings from chocolate blood agar slant cultures of *B. influenzæ* (⅛ to 1 slant) in each nostril. Two others received the peritoneal exudate from a monkey with *B. influenzæ* peritonitis (0.1 c.c.) in each nostril. The last two received a six hour chocolate blood broth culture of *B. influenzæ* (0.5 c.c.) in each nostril. Five of the six volunteers developed definite signs of infection, premonitory symptoms appearing four to six hours after inoculation. Headache and general malaise were soon followed by rhinitis, pharyngitis, and mild conjunctivitis, and in three instances by tracheitis. Backache was present in two cases; general muscular aching in two. Definite leucopenia was noted in three cases; in the other two the leucocytes were unaffected. Fever was absent in all five cases. Two of the patients were confined to bed for 24 to 48 hours. The symptoms lasted two to four days, except in one of the tracheitis cases in which they persisted for ten days. Strange to say, the *B. influenzæ* carrier developed signs of infection but this ran a mild course. Smears from nasal discharge and from sputum of infected cases showed pus cells and influenza bacilli, sometimes in large numbers. Cultures gave influenza bacilli, often in practically pure culture. In several cases, influenza bacilli persisted in the secretions two weeks or more after inoculation. None of the volunteers developed pneumonia.

Further Studies on Influenza.—Dr. E. C. ROSENOW of Rochester, Minn., presented this paper. He said that the importance of the streptococci, including the pneumococci, during the epidemic of 1918, had been emphasized. Injections of streptococci were followed by a leucopenia corresponding to the leucopenia in the patient from whom the strain came. In the epidemic of 1918 there was a high mortality rate early in the epidemic, but later the character of the disease changed markedly. In experimental work the organism was found to change with animal passage. The pathologists also noted a change in the character of the lung lesions which occurred early and late in the epidemic. The strains tended to lose in virulence. The second animal passage was most virulent in the trachea; in the peritoneum virulence was high and remained high. From a careful study of the statistics of the epidemic it was quite evident that the changes in mortality were very largely due to changes in the virulence of the microorganism.

Dr. C. H. BUNTING of Madison, Wis., said that in 1920, in the epidemic in Madison, daily blood counts were made to throw light on the leucocytic findings. There was an almost immediate leucopenia and inhibition of the marrow cells. In the lung cases there was immediate leucocytosis which occurred before the clinician could tell what had happened. This coincided with the first clouding of the lung in the *x*-ray picture. It would seem that there was inhibition of the marrow, as in typhoid fever. It was found that the bacillus of Pfeiffer produced most profound bone-marrow changes in rabbits. Evidence would seem to be rather in favor of the Pfeiffer bacillus, than of the pyogenic cocci, on account of the bone-marrow picture.

Dr. KOBER of Boston said that he thought it might be of value to recall facts as to the epidemic constitution of the atmosphere. This was evident in malaria and scarlet fever. In agriculture there was a great difference in the quality and quantity of crops of vegetables and fruits which was attributable to meteorological influence. Why should not a similar influence have an effect on unicellular organisms?

Dr. JOS L. MILLER of Chicago said that a leucopenia was noted in a streptococcus epidemic associated with measles. There was frequently leucopenia in streptococcus pneumonia.

Dr. E. C. ROSENOW, in closing, said that contact played an important part in the epidemics, though the reason was not known. There was increase and decrease in the virulence of organisms. The type of reaction in the animal might change completely although the organism was the same throughout. To draw the conclusion that the oncoming leucocytosis with the occurrence of the pneumonia was due to a secondary invader, might not be true. Prolongation of resistance might change the organism so that there was no leucopenia, but a leucocytosis instead.

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading; but this is with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

HERMAN'S DIFFICULT LABOUR. Revised and enlarged by CARLTON OLDFIELD, M.D. 573 pages with 198 illustrations. Published by William Wood & Company, New York.

TEXT-BOOK OF OPHTHALMIC OPERATIONS. By HAROLD GRIMSDALE, M.B. Second Edition. 438 pages with illustrations. Published by William Wood & Company, New York.

THIRTY-FIFTH ANNUAL MEDICAL REPORT OF THE TRUDEAU SANATORIUM, together with Tuberculosis Studies. 127 pages.

ADVANCED LESSONS IN PRACTICAL PHYSIOLOGY. By RUSSELL BURTON OPITZ. 238 pages with illustrations. Published by W. B. Saunders Company, Philadelphia.

THE DAWN OF MODERN MEDICINE. By ALBERT H. BUCK, M.D. 288 pages with illustrations. Published by Yale University Press, New Haven.

WIENER ARCHIV FÜR INNERE MEDIZIN. By RUDOLF KAUFMANN, M.D. 242 pages. Published by Urban & Schwarzenberg, Berlin and Vienna.

THE MEDICAL CLINIC OF NORTH AMERICA. May, 1920. 306 pages with illustrations. Published Bi-Monthly by W. B. Saunders Company, Philadelphia.

ANNUAL REPORT OF THE UNITED FRUIT COMPANY (MEDICAL DEPARTMENT) 1919. 95 pages. Printed by the Press of Geo. H. Ellis Co., Boston.

TWENTY-THIRD ANNUAL REPORT OF THE LOOMIS SANATORIUM for the year ending October 31, 1919. 95 pages with illustrations.

KLINISKE LINSESTUDIER. By HARALD G. A. GJESSING. 354 pages. Published by Harald Lyche & Co.

THE GREAT WAR AND THE R. A. M. C. By Lt.-Colonel F. S. BRERETON. 300 pages with 9 maps, 1 plan and 2 appendices. Published by E. P. Dutton & Co., New York.

TRANSACTIONS OF THE AMERICAN PEDIATRIC SOCIETY. Volume xxxi, 1919. 270 pages with illustrations.

ANATOMIE DES MENSCHLICHEN GEHIRNS UND RUCKENMARKS. By PAUL FLECHSIG. 121 pages with illustrations. Published by George Thieme, Leipzig.

THE FACULTY OF THE COLLEGE OF PHYSICIANS AND SURGEONS. By DORIS U. JAEGER. 24 portraits. Published by Paul B. Hoeber, New York.

HEART TROUBLES, THEIR PREVENTION AND RELIEF. By LOUIS FAUGERES BISHOP, M.D. 422 pages, with illustrations. Published by Funk & Wagnalls Company, New York.

UNIVERSITY OF IOWA STUDIES. Vol. 1. No. 6. June, 1920. Published by the University, Iowa City.

X-RAY OBSERVATIONS FOR FOREIGN BODIES. By HAROLD C. GAGE. 83 pages, with illustrations. Published by C. V. Mosby Company, St. Louis.

RADIOGRAPHY. By ROBERT KNOX, M.D. 64 pages, with illustrations. Published by C. V. Mosby Company, St. Louis.

CANADA'S WORK FOR DISABLED SOLDIERS. 149 pages, with illustrations. Issued by the Department of Soldiers' Civil Re-establishment, Ottawa.

CARE AND FEEDING OF INFANTS AND CHILDREN. By WALTER REEVE RAMSEY, M.D. 290 pages, with 123 illustrations. Published by J. B. Lippincott Co., Philadelphia.

THE PRINCIPLES OF ANTENATAL AND POSTNATAL CHILD PHYSIOLOGY. By W. M. FELDMAN, M.D. 693 pages, with 6 plates and 129 illustrations. Published by Longmans, Green & Co., New York.

THE SURGICAL CLINICS OF CHICAGO, June, 1920. Vol. 4. No. 3. 202 pages. with 52 illustrations. Published by W. B. Saunders Company, Philadelphia.

THE USE OF COLLOIDS IN HEALTH AND DISEASE. By ALFRED B. SEARLE. 120 pages. Published by E. P. Dutton & Co., New York.

HUMAN PARASITOLOGY. By DAMASO RIVAS, M.D. 715 pages, with illustrations. Published by W. B. Saunders Company, Philadelphia.

Therapeutic Hints.

Nausea and Vomiting of Pregnancy.—C. Henry Davis gives the following plan of treatment: (1) A carefully taken history will usually reveal any previous gastro intestinal disturbance, nervous disorder, or other physical conditions which might make the patient more sensitive to the disturbed metabolism of pregnancy. The physical examination will reveal any source of local irritation or infection, which is to be removed. Pus pockets, infected tonsils, bad teeth, uterine displacement, and acute cervicitis may tend to increase the nausea and vomiting of pregnancy, but should be regarded as predisposing rather than causative factors. (2) Put the patient to bed if vomiting is severe. It may be sufficient to keep the milder cases in bed until one or two hours after breakfast, but when possible it is better to keep them there until noon. (3) Use an anti-acid dry type of diet such as is used in the nervous type of vomiting among the non-pregnant. Allow no liquid within the hour before meals or the first one and one-half hour after. The patient may have enough milk to moisten her cereals but no other liquid. This diet should be high in carbohydrate and low in fats and proteins. Milk may be taken between meals. (4) At least three pints of water daily, preferably alkaline water, is given between meals. Pineapple and orange juice may be given. (5) Alkalinize the system by the use of alkaline water or sodium bicarbonate. The alkaline treatment continued throughout pregnancy. (6) Stomach lavage may be needed. This may be accomplished by having the patient drink several glasses of tepid water each containing one-third teaspoonful of baking soda. (7) Sodium bromide is of value in the cases not controlled by the simple change in diet and alkaline treatment. Ten to fifteen grains may be given in a little hot water thirty minutes to one hour before taking food. Cerium oxalate, two grains every half hour for three consecutive doses, is at times useful in cases of simple nausea, but is of no value in the more severe. The use of cocaine is not favored. (8) Corpus luteum extract is administered hypodermatically when there is a history suggesting ovarian insufficiency, and in cases with a history of early abortions. (9) Cases approaching the pernicious stage require a special nurse and should be in a hospital. If seen early before the marked dehydration and severe acidoses, stop all food and liquid by mouth and give 2 per cent to 5 per cent glucose solution per rectum. A retention enema of 250 c.c. of the glucose solution containing from 30 to 60 grains each of sodium bromide and sodium bicarbonate may be given. As the nervousness is controlled reduce the bromides to 30 grains. After twenty-four to thirty-six hours, the patient may be allowed very small amounts of fluid and later solid food by mouth. Fluid may also be given by means of a duodenal bucket as advocated by Kanavel in 1916. (10) Severe cases seen after marked dehydration is present should have 800 to 1000 c.c. of normal saline solution under the breasts. When possible, they should have an 18 or 20 per cent glucose solution in triple distilled water given intravenously according to the technique of Woodyatt, Wilder, and Sansum.—*Wisconsin Medical Journal.*

DILATATION OF THE BRONCHI.

A REVIEW OF FORTY CASES OBSERVED JUNE, 1918—JUNE, 1919.*

BY JABEZ H. ELLIOTT, M.B.,

TORONTO, CANADA.

LIEUTENANT-COLONEL C.A.M.C.

ALTHOUGH dilatation of the bronchi was mentioned by Störck in 1761, the first anatomical and clinical account of the disease was given us by Laennec in 1819. In his first edition he says: "The organic lesion which I am about to notice seems to have been hitherto entirely overlooked both by the anatomist and the practitioner." He then proceeds to give "a short account of this rare lesion," and details two cases furnished him by M. Cayol, who as a medical student in 1808 first directed his attention to the affection. Six years later, in his second edition he writes: "The dilatation of the bronchi without being a very common affection, is, however, much less rare than I long conceived it to be . . . within these last six years I have met with a great many instances of it."

The frequency with which this disease is confounded with tubercle of the lung and chronic bronchitis has led me to record some of the cases which I have seen during the past year. It is not a rare disease and its presence is frequently overlooked. The cases reported represent most but not all of the cases seen during this period.

A number of case histories have not been available for this short review. Most of the cases were returned soldiers paraded before me for recommendation as to disposal. The remainder were cases seen at the special chest clinics at St. Michael's Hospital and the Hospital for Sick Children, with five from other sources.

I shall not attempt within the limits of this paper to discuss morbid anatomy or the treatment of the affection.

The disease is usually secondary to disease of the bronchial wall, lung, or pleura. J. K. Fowler, in a study of 35 cases with autopsy reports at Brompton Hospital during a period of seven years, analyses the origin thus:

	No. of Cases
Acute bronchitis	1
Chronic bronchitis	7
Syphilitic stenosis of the bronchi	1
Pressure on bronchi by a mediastinal growth or an aneurysm	1
Foreign bodies in the bronchi	2
Bronchitis and asthma	1
Bronchopneumonia	5
Lobar pneumonia	2
Chronic pneumonia and cirrhosis of lung	5
Pulmonary tuberculosis	4
Pleurisy and empyema	3
Hydatid cyst of the kidney	1
Spinal curvature	2

*Read at the 35th annual meeting of the American Climatological and Clinical Association.

Lord of Boston and Boggs at Johns Hopkins have published cases which point to influenza as a causative factor, and the studies of influenza in the epidemic of last winter have shown us the intense inflammation and destruction which take place in the bronchioles in the virulent forms of this disease. In the severe cases which have recovered we may expect that some at least will have permanently damaged bronchial walls and numerous cases of dilatation will surely develop.

In gas poisoning, bronchiectasis has occasionally resulted, doubtless from the damage done to the bronchi and aided by a degree of pulmonary fibrosis which has followed the purulent bronchopneumonia or bronchiolitis which was not infrequent after chlorine and mustard gas.

Diagnosis is summarized thus by Samuel West: "For the diagnosis of bronchiectasis we require (1) evidence of the existence of a cavity, and (2) reasons for believing that the cavity is a dilated bronchus. The first may be a matter of fact, the second of opinion, and thus the diagnosis of bronchiectasis must in the nature of things be nearly always uncertain and often impossible. The bronchiectatic organ of the cavity is a matter of opinion only, and if it be difficult, as it so often is, after death, even with the help of the microscope, to decide the question, it must be frequently impossible during life.

"Stokes laid down the rule that when the signs of cavity had existed long without change, and without the development of phthisis, especially if the cavity were in the base of the lung, the diagnosis of bronchiestasis was justified. It is at any rate upon these data that the diagnosis is usually made, but as no account is taken of the fact that similar cavities may develop as the result of suppuration or gangrene after pneumonia or in the course of chronic tuberculosis, the data are obviously insufficient. It is always misleading and often incorrect to speak of such cavities as bronchiectatic, and it would be more accurate to describe them by the term chronic excavation of the lung, which in fact involves no theory."

The diagnosis of bronchiectasis when such marked clinical signs are present, can usually be made, though difficult when the lesions are apical as illustrated by the cases recorded by McCrae and Funk. A generation ago the diagnosis of tubecle of the lung was rarely attempted except in the presence of cavity signs or of grave constitutional symptoms associated with changes in percussion note and on auscultation. Yet with practically no addition to

our armamentarium other than the demonstration of the tubercle bacillus, earlier diagnosis was made and to-day even before the appearance of positive bacteriological findings and in the presence of only slight physical findings we do not hesitate to make an early diagnosis.

The time has come when the diagnosis of dilatation of the bronchi may frequently be made in absence of definite cavity signs. Only within the past three years is there anything to be found in the literature of the subject to help one in diagnosing the condition early. Ewart in Allbutt and Rolleston's "System" considers that when originating in a general bronchitis, dilatation in its earlier stages can only be inferred. As to its differentiation from phthisis, he considers that bacteriological examination of the sputum now decides the question after consideration of the clinical history, the general clinical state and aspect and the physical signs. McPhedran, in his excellent article in Osler's "Modern Medicine," also emphasizes the value of history in the diagnosis. With careful attention to these points as outlined, a diagnosis can in many cases be inferred long before the presence of physical signs of extensive or long-standing disease.

When the presence of the disease is inferred, the diagnosis can, in the majority of cases, be confirmed by the *x*-ray examination. It is only in recent writings that the value of the *x*-ray has been pointed out. In a valuable text book on the *x*-ray brought out only last year in English, the statement is made that the *x*-ray is practically of no service in the diagnosis of this disease and this appears to be the attitude of most writers on respiratory disease, even of recent years. This, I am certain, is due entirely to the use of the single plate which is of value only in the case of large dilatations or of dilatations of the main bronchi. Even the stereoscopic plate as produced in many hospitals is of little service; frequently the plates lack the detail necessary for outlining the bronchial tree, but roentgenograms of the chest, properly made, usually show the dilatations beautifully, and after seeing what can be done by an expert operator, one cannot fail to recognize what an enormous waste is going on in the production of inferior work, which fails to demonstrate this not infrequent bronchial lesion. Stereoroentgenograms are as important in the diagnosis of early or deep-seated bronchiectasis as is the tubercle bacillus in the absolute diagnosis of tubercle of the lung.

CASE I.—Ray, S. G. October 23, 1918: Had bronchitis on enlistment and the cough has not since cleared. The chest shows no signs of disease but in view of his persisting cough *x*-ray plates have been ordered. Stereo-*x*-ray plates show bronchioles left upper lobe dilated longitudinally. Saccular dilatation of bronchioles in left middle and lower areas near the hilus and extending into the lower lobe. None of these dilatations extend far from the hilus. Left hilus, upper and lower, shows heavy cotton wool shadowing with radiations. Right hilus shows markings branching into the right interscapular area with a few small nodes, which are also present in lower lobe branches on the right. Right diaphragm clear but irregular.

Diagnosis: Chronic bronchitis with bronchiectasis.

CASE II.—Pte. Chapple. Age 30 years. Spent four months in hospital with diagnosis tubercle of lung, onset with pleurisy. Half of time in bed, half as an up patient with transient fever. No tubercle bacilli any time present. July 7, 1918: General condition fair. Weight stationary, with loss of 20 per cent. Morning cough, varies with posture. Dyspnea on exertion. Pain left lower chest. Working ability six hours. Sputum one ounce, fetid, periodic, increased lying down. Tubercle bacilli found while under observation.

Physical examination shows slight retraction, lower left chest with inspiratory indrawing sixth space. P.M.I. fifth space, nipple line. Localized dulness fifth and sixth spaces with faint breath sounds with constant consonating râles and sibili. Slight clubbing of fingers. *X*-ray shows bilateral dilatation of bronchi. Multiple bilateral saccular about right and left hilus but most marked in left, also right from hilus to base. Evidence of old tubercle about the hilus.

Diagnosis: Tubercle of lung with bronchiectasis about hilus but particularly left lower lobe.

CASE III.—Pte. P. G. Age 20 years. Height 62 in. Weight 175 lbs. Two years ago inflammation of lungs, in bed over a month, since then well until June, 1918, three months after enlisting, when following exposure on route march, took cold, and cough has persisted. July, hæmoptysis. 2 ounces. Physical examination. September 8, 1918: Right supra-clavicular fossa deeper than left. V.R. and V.F. slightly increased over right lower lobe behind. Breathing harsh over right side with prolonged expiration at right apex. Moist râles brought out by coughing over right lower lobe behind. Sputum examination negative for T.B. Temperature over 21 days (July 20-August 9) subnormal except for rise to 99.2° on August 6, when he had a hemorrhage. Referred M.D. No. 2 as tubercle of lung.

October 10, 1918: Nothing abnormal found on examination beyond slightly impaired resonance in left first and second interspace. Adventitious sounds are absent. Finger tips are cyanosed with swelling at back of nails. *X*-ray plates show dilatation of bronchus near the hilus on both sides. His present condition is due to chronic bronchitis which is complicated by bronchiectasis. Sputum negative for T.B. Temperature range normal. Lost 12 pounds weight. Cough in mornings with 2 drachms grayish phlegm. Slight feeling of general weakness.

Diagnosis: Bronchiectasis about right and left hilus with hilus tubercule.

CASE IV.—Bandsman M. June 29, 1918: Has had cough one year. Of late has had frequent hæmoptysis, one drachm to one ounce. Cough frequent. Sputum one ounce daily, influenced by postural change. The overseas diagnosis was bronchitis with debility. Physical examination shows marked general emphysema with left basal pleurisy and high adherent diaphragm. Fingers are slightly clubbed. *X*-ray examination shows general heavy shading of bronchial tree. Dilated bronchi in left lower lobe with shadows suggestive of old hilus tubercle.

CASE V.—Pte. B. C. S. Age 45 years. 60 in. 133 pounds. Heavy colds every winter for past six years. Became worse with wet weather in England. Returned to Canada because of bronchitis. June 28, 1918: Weakness, persistent cough and shortness of breath on moderate exertion. Sputum two ounces daily, mucopus, odorless. Sternum is rather prominent. Deep antero-posterior diameter. There are localized râles with slight dulness in second right interchondral space also below fourth rib right anterior and lateral. There is marked clubbing of fingers and thumbs and great toes. No T.B. in sputum. Temperature normal. Has chronic cough. Wassermann—negative. *X*-ray plate shows bronchiectasis right upper lobe second space also in right lower lobe out from hilus, about left hilus also the bronchi of left lower lobe are dilated. Right diaphragm high.

Diagnosis: Bronchiectasis, right upper and lower lobes, and about left hilus.

CASE VI.—Lieutenant R. M. October 12, 1918: He states he had a slight cough last autumn and carried on until his trench fever and shell gas poisoning in November. He has about one-half ounce mucoid sputum and sleeps poorly. He is short of breath on exertion and has lost 20 to 25 pounds in weight. His condition is probably aggravated by exposure following the torpedoing of his ship en route from England. On examination the chest is flat and both apices narrowed and dull on percussion, especially on the right. Breath sounds are normal, but there are fine râles over the left clavicle. Percussion resonance is impaired on each side

to the second rib. Repeated examination of the sputum showed no tubercle bacilli. *X*-ray plates indicate a quiescent healed tuberculosis of the right upper lobe, chronic bronchitis with bronchiectasis in the right upper lobe.

CASE VII.—Cpl. F. E. G. Age 26 years. Subject to winter colds. Had pneumonia three times before enlisting. Influenza August 10, 1918, at Niagara Camp, followed by pneumonia. June 12, 1918: Troublesome cough. Sputum becoming free. Good color. Nutrition fair, though says he has lost 30 pounds of which has regained 6 pounds. Left chest lags and moves less than right. Resonance impaired below fifth rib anterior, sixth axilla, sixth posterior. Little movement of lower border of left lung. Showers of moist râles over whole left lung after cough, greatest at lower part and superficial. February 25, 1919: No elevation of temperature. Still many superficial crepitations over lower lobe apices posteriorly. Examination of sputum shows presence of many bacteria—pneumococcus, staphylococcus, *streptococcus catarrhlis*, etc. No tubercle bacilli. March 7, 1919: Poor movement of lower border of left lung anteriorly, few crepitations axillary line. *X*-ray shows slight scoliosis to left. Left Diaphragm high. Heart displaced to left. Right hilus, heavy and matted. Vertical bronchus and first and second interspace branches are heavy with few densities, small, at bifurcations. Lower lobe trunks are heavy and wide and matted in inner third. Left bronchial tree from first space is heavy and trunks are irregularly wide, especially anterior branches which can be traced to periphery where pleura appears thickened.

Diffuse bronchiectasis of middle area of left lung. Slight about right hilus. There are old tuberculous deposits. Sputum examination. February 28, 1919, tubercule negative, January 3, 1919, mucopurulent, polymorphs + +, monos. + +, epith. + +, Gram. + cocci + +, streptococci + +, pneumococci + +, catarrhalis Gram + bacilli + +. Eight subsequent examinations of sputum, tubercle negative.

CASE VIII.—Gunner H. D. W. Age 20 years. Height 67 in. Weight 127 lbs. Cough persistent since pneumonia, 1917. Treated in hospital and sanatorium for one year as tubercle of lung. August 23, 1918. General condition fair. No loss of weight. Marked weakness associated with prolonged rest in bed and frequent severe hæmoptysis. Cough rather continuous. Sputum two ounces daily usually intimately mixed with pink. Frequent hemorrhage one to four ounces, odorless. No T.B. at any time. The patient is pale, but well nourished. Physical signs almost nil. Few rhonchi posterior left, disappeared with cough. *X*-ray shows marked widening of the large bronchi in both lower lobes.

Diagnosis: Bronchiectasis. No definite evidence of tubercle.

CASE IX.—Pte. T. C. 30 years. 69 inches. 140 pounds. Bronchitis began in England, 1900. Was in a sanatorium nine months. Came to Canada following spring, where he made marked improvement. Had a slight winter cough subsequently but not troublesome until he enlisted and went to England in 1916. Complains of weakness, and shortness of breath after slight exertion such as going up stairs and walking fast. Coughs a good deal, especially in the mornings, with expectoration, two ounces of dark yellow mucus. High sternum above, clavicles prominent. Chest movement fair, same on both sides. No definite dullness, no bronchial breathing. Diffuse sibilant râles at apices and bases, no moist râles; no clubbing of the fingers. No record of fever. Repeated sputum examinations T.B. absent. *X*-ray stereo shows lung quite clear. No heavy deposits to suggest tubercle. Bronchial tree shadow rather heavy in lower lobes with dilatation in the right tree.

CASE X.—Gunner F. W. G. Age 28. 69½ in. 136 pounds. Health good prior to enlistment though always subject to colds. Admitted to hospital, England, January 18, 1918, as purulent bronchitis. Invalided to Canada, May, as bronchitis. October 22, 1918: Shortness of breath after slight exercise, slight cough, sputum has gradually lessened, only a trace. Had pain in subclavicular region, none now. Expansion fair and equal. Harsh breathing under left clavicle. No dulness. No adventitious sounds. Stereoscopic plates show dilatation of large bronchi left and right. Repeated sputum examinations show no tubercle bacilli. Wassermann: Negative.

CASE XI.—Pte. J. M. Age 20 years. January 11, 1919: Cough has persisted for one year. Influenza overseas eight months ago while in hospital in England with G. S.W. left forearm. Loss of weight 14 per cent. Cough particularly at night, varies with posture. Sputum one drachm, periodic, no blood, more lying down. T.B. absent on repeated examinations. Pain upper and lower left chest. Physical examination—Friction rub left infrascapular with high diaphragm, restricted excursion. An area over left third rib anteriorly with a few râles after cough. Fingers and toes clubbed. Because of wasting of muscles clubbing appears greater in left hand. *X*-ray stereo shows unilateral multiple saccular dilatations about upper pole left hilus associated with numerous small calcareous shadows, diaphragm fixed with slight pleural thickening at base. Left vertical bronchus mottled. Pulmonary area clear.

CASE XII.—Pte. Fitz. Age 30. Two months ill 1903 lead poisoning. Pneumonia at Valcartier, 1916. To France November 3, 1917. Became wheezy and short of breath. Sent to England as G.S.W. arm and asthma, November 1, 1918. Invalided to Canada with amputated right arm and tubercle of lung. Six months in hospital. An up patient with transient fever. July 10, 1918: Working ability, nil. He is thin, weak. Almost continuous cough. Sputum not varying with posture, three ounces, particularly morning, odorless. No T.B. on repeated examinations.

Physical examination shows moderate emphysema. Impaired resonance to second rib right and left with little movement. Both S.S. fossæ dull. No râles. Localized area left infrascapular with dulness, bronchoves. breathing and constant, localized small râles. Marked clubbing of fingers. Slight clubbing of toes. Stereo-*x*-ray shows old tuberculous lesion left and right apex with bilateral cylindrical and saccular bronchial dilatations in right and left upper lobes and also in left lower lobe. Numerous calcareous shadows in hilus. Right diaphragm slightly blurred.

Diagnosis: Bronchiectasis with healed tubercle of lung.

CASE XIII.—Pte. F. H. F. Age 22 years. April 24, 1919: Pleurisy and pneumonia at age of five years. Family moved from England to Canada on account of this boy's health, three years later. Since coming to Canada has had no illness but has always had cough and sputum. Dyspnœa on exertion and frequent colds with only temporarily increase of sputum. Enlisted early in 1916, went to England, August, 1916; France, December, 1916, and carried on in line until gassed in September, 1918. Invalided to England. Severe gas poisoning. Discharged from hospital February, 1919, and returned to Canada for demobilization. There is considerable cough and one ounce purulent sputum daily. There is about eight pounds loss of weight. Fingers are somewhat short and stubby.

Chest: Right lower chest moves less than left. Impairment of resonance over whole right chest especially from apex to second rib and to spine of scapula, and below fourth rib in front and eighth rib, posteriorly. Whispered voice increased over right upper lobe and expiration prolonged with a few whistling rhonchi. Over lower dull area many medium moist râles are heard; expiration not especially prolonged. No marked difference in vocal fremitus or resonance. Right diaphragm is high and adherent. *X*-ray shows many dilated bronchi.

Diagnosis: Bronchiectasis and fibrosis of right apex.

CASE XIV.—Pte F. H. R. Age 31 years. 65 In. 142 pounds. Patient has had cough and sputum since 1903 when he had "slow pneumonia," in bed 6 weeks. Has had "pneumonia" on several occasions, but only ill for a few days. Some cough has persisted. He has never lost weight except for a short time while in France. He has convergent strabismus of left eye antedating enlistment. There is slight stammering which dates from childhood. There is moderate amount of cough and very small amount of purulent sputum. There is dyspnea after moderate exertion. There is marked retraction of left chest with very little movement during respiration. There is heaving praecordial pulsation extending out to axillary line in fifth inter-

space. The right side of the subcostal angle is much greater than left. There is high pitched skodaic resonance with bronchial breathing and no râles over the left upper chest with absolute dulness below fourth rib in front. There is evidence of large cavity extending from axillary region at level of fourth and fifth ribs to scapular region at level sixth and seventh ribs. Cracked pot resonance, metallic râles, amphoric breathing, pectoriloquy. The fingers are slightly clubbed.

Diagnosis: Fibrosis of left lung with bronchiectasis.

CASE XV.—Pte. L. M. Age 30 years. 65 in. 118 pounds. Cough dates from May, 1917, with history of chronic bronchitis. September 25, 1918: There is considerable cough with morning expectoration which is purulent and sometimes sanguineous. There is considerable wheeziness. Dyspnœa is present after moderate exertion, *e.g.*, running 30 yards.

Sputum about two ounces in 24 hours. There is moderate clubbing of fingers. Chest is semi-rigid with moderate kyphosis. There is some impairment of resonance of right upper lobe. Breath sounds are every where harsh with sonorous and sticky râles, heard both behind and in front of chest, especially over lower lobes posteriorly. *X*-ray shows multiple bronchiectasis about hilus and portions of both lower lobes. Sputum has never shown tubercle bacilli.

Diagnosis: Bronchiectasis, principally lower lobes right and left, with emphysema.

CASE XVI.—Pte. D. M. Age 32 years. 69 inches. 137 pounds. Enlisted May, 1915. First taken sick in February, 1918, with cough and pains in chest. Was sent to hospital in France and then to England.

April 2, 1919.—Is not feeling up to his general health; coughs a great deal during the day and night, expectoration one cup yellow green phlegm, odor is foul. Sleeps fairly well and is propped up in bed, which gives him relief. Shortness of breath on climbing flight of stairs slowly. Pulse 82, resp. 20, sitting; touching ground 10 times, P. 120, resp. 26, with distress, returns to original in 1½ minutes. Apex beat at nipple line.

The man is rather poorly developed and nourished. Has cyanotic tint to face. Marked clubbing of fingers. Breath very foul. Chest emphysematous, moving as a whole. General hyper-resonance, cardiac dulness almost lost. Numerous râles heard posterior part of chest, disappearing on coughing. Stereo plates show right hilus dense, lower pole heavy and heavy bronchial roots to lower lobe. Bronchus heavily shaded and appears to have an irregular diameter. Left hilus somewhat heavily shaded but less than right. In area between fourth space anterior and eighth space posterior are mottled shadows of irregularly dilated bronchi. Lower lobe bronchial tubes overlying heart shadow show cylindrical dilation. Left first costal cartilage calcified, more so than right.

Diagnosis: Bronchiectasis. Disability practically total because of very troublesome cough and odor present in sputum.

CASE XVII.—Pte. E. A. W. S. Age 29 years. [illegible] in. Weight 142 lbs. Has been subject to winter colds for years. Has not been without cough and sputum since he went to England, June, 1917. Pleurisy of left side, February and March, 1918. Examination on February 18, 1919. There is cough with purulent sputum about 2 oz. in 24 hours. There is dyspnea after moderate exertion, *e.g.* running 50 yards. Sputum has never shown presence of tubercle bacilli. There is a fetid odor to the sputum and to the breath after coughing.

Fingers are clubbed. Hands are cyanotic. Right chest is slightly smaller than left, with slight droop of right shoulder. Right nipple lower than left but right subcostal angle is not narrowed. Slight diminution of expansion of right chest. There is slight change in percussion note over left lower lobe; there is a blowing quality to inspiration around angle of left scapula and rhonchi are heard with cough in this area and around axilla. Stereo-*x*-ray of chest shows diaphragm normal, moderate scolosis, convexity to right, in region seventh, eighth and ninth ribs. Right upper chest slightly smaller than left; Right hilus is heavy with fluffy shadows in lower pole. Upper three-quarters right lung is fuzzy with bronchial trunks faintly outlined. Lower trunks are matted. Lower lung area is clearer than normal. Left hilus shows fluffy shadows with a number of calcareous shadows well out. Vertebral trunk is dilated to apex. Middle area of left lung —bronchial trunks difficult to trace because of irregular shading. Lower lobe trunks are heavy and blur outline of heart shadow. They appear definitely dilated from fourth to seventh rib outside heart shadow and especially in cardiophrenic angle.

Diagnosis: Diffuse bronchiectasis of left lower lobe and generalized bronchitis.

CASE XVIII.—Spr. E. J. P. Age 17 years. Invalided to Canada as tubercle of lung. March 11, 1919: Cough slight, when he walks fast it is worse, spits up a brownish sputum, never coughs at night or in the morning. No night sweats. Weight increasing. Repeated sputum examination show no T. B.

March 13, 1919.—Expansion equal and good 3 inches, chest well-formed, symmetrical, very slight impairment resonance, right, down to third rib. Right diaphragm high but freely movable. Right front from third to sixth rib and along same level in axilla a few bubbling or gurgling râles, increased after cough. In this area whispered voice is increased. On left side, middle and lower areas, an occasional piping rhonchus is heard.

A provisional diagnosis was made of chronic bronchitis with bronchiectasis. With cough persistent since childhood and no increase on service, to T.B. found at any time and physical signs principally in lower lobes, absence of fever during months of observation, diagnosis of tubercle of lung is not concurred in. History of having hemorrhage fits in with bronchiectasis. *X*-ray shows moderate high diaphragm, normal shape, broad heart shadow, right border lost in heavy right hilus shadow. All bronchi about right hilus show dilatations, some extending well out into the middle pulmonary area and along vertical bronchus well to the apex. On left side also sacculated dilated trunks close to hilus. The left vertical bronchus is mottled as well as dilated. The picture is one of bronchiectasis about the hilus but extending into lung on right side, possibly some old inactive peribronchial tubercle about the vertical bronchi.

Diagnosis: Bronchiectasis, present on enlistment but aggravated by service.

CASE XIX.—Pte. W. L. C. Age 33 years. March 13, 1919. Has lived in California and Mexico for past seven or eight years. Was born in Regina and went South because he was subject to colds. In the South he was comparatively free of colds. On the way to England in April, 1918, he caught cold and was unable to get rid of it. Soon after arrival began spitting up blood,—streaking of sputum. Was sent to hospital, Bramshott, about June 1—diagnosis hemoptysis. While there frequent examinations of sputum never showed presence of T.B. but streaking of sputum continued. Last noticed in sputum about one week ago. Cough is variable and spasmodic. Becomes very troublesome after a fresh cold of which he has had four in last month. Sputum is much increased after colds and is usually blood streaked. Amount at present is about one-fourth sputum cup.

April 3, 1919.—Complaining to-day of steady cough, spits up some clots of blood and a good deal of yellow mucus or brown stained sputum. No night sweats. Weakness after walking brings on severe coughing spells. There is wheezing frequently in A.M.

Chest: Wide subcostal angle, short and broad chest. Semi-rigid. There is impaired resonance of right apex down to third rib with prolonged expiration and a few rhonchi. Posteriorly over right lower lobe are many whistling rhonchi which clear with prolonged coughing. Similar over lower lobe of left lung but less marked on right side. *X*-ray shows dilated bronchi about right hilus, some dilatations about left.

Diagnosis: Bronchiectasis.

CASE XX.—Spr. H. C. Age 20 years. June 21, 1918: Had spent two years in hospital and sanatorium as tubercle of lung. Pleurisy left base at 14. Examination shows the general condition good. Working ability one-quarter. Slight weakness. Loss of weight 5 per cent. Dyspnea on exertion. Pain lower left chest. Sputum two ounces, fetid, periodic, more on lying down and especially on back. Many organisms present. No T.B. at any time. Slight dulness with cavernous breathing and consonating râles in localized area fourth to sixth

space, left anterior. Left infrascapular slightly dull with distant cavernous breathing and bronchophony. Slight clubbing of fingers, none of toes. No fever recorded during two years in hosiptal. *X*-ray shows left upper main bronchus dilated, heavy left hilus with multiple localized dilatations in left lower lobe. Shadow of calcareous deposit in left hilus.

Diagnosis: Bronchiectasis left, particularly lower lobe.

CASE XXI.—G. Wilkins. Age 40 years. January 31, 1919. Nine months in hospital. No previous illness. Three months in bed. Began with symptoms of chronic bronchitis. Sputum more on lying down. T.B. absent on all examinations. Fetid odor. Marked clubbing of fingers and toes.

Physical examination shows an area of impaired resonance about and below inferior angle of left scapula with coarse bubbling râles almost consonating, with bronchial breathing. Chest generally barrel shaped with area C.D. lost. *X*-ray shows multiple saccular dilatations in left lower lobe well out from hilus with dilatation of the larger trunks.

CASE XXII.—H. M. Age 26 years. Height 67½ inches. Weight 140 pounds. Three years ago weighed 163 pounds; 1 year ago, 146 lbs. Gassed, 1916. Invalided home. Discharged March, 1917. States he was cured of chest trouble before re-enlisting in June, 1917. Influenza, May, 1918. March 3, 1919: Patient states that he has had a cough for over two years with small quantity of sputum; says he has blood in sputum once or twice a week. Some difficulty in breathing at times. States he lost 42 pounds following influenza last May. Feels nervous all the time. Since influenza appetite has been poor. Nauseated at times and has vomited once or twice. Formerly had some gastric disease but this has disappeared.

Physical examination shows nutrition fair and color good. Expansion fair and equal. Negative on percussion and auscultation except for an occasional sonorous râle. Heart sounds clear. Pulse 90 at rest, 120 after exercise, touching floor 12 times. Resp. 32 with some dyspnea. Patient coughs frequently.

March 11, 1919. Sputum is blood stained—with small clots and a pinkish tinge to whole—several examinations negative to tubercle.

April 22, 1917. Chest is semi-rigid. No retraction or impairment of resonance, equal and fair expansion of chest. Lung borders move well. Few sonorous râles heard over both lungs posteriorly, otherwise respiratory murmur is normal. *X*-ray shows bronchial tree well outlined with definite dilatations of bronchi in lower lobes especially in right. No evidence of tubercle of lung. Sputum is blood tinged especially after "colds," which are frequent. Examination of sputum is negative for tubercle but contains considerable flora of pyogenic organisms. Pulse at rest 76; after flight of stairs, 104. Returns in one minute with slight respiratory distress. There is cough with mucopurulent blood stained sputum, 3 oz. in 24 hours. There is some substernal pain at nights, worse after a fresh cold. There is dyspnea after exertion, *e.g.* running 75 yards.

Diagnosis: Bronchitis with bronchiectasis.

CASE XXIII.—Pte. J. C. M. Aged 20 years. Height 68 inches. Weight 126 pounds. No previous illness. Gassed September 7, 1918. Medical sheet records conjunctivitis, laryngitis, burns of scrotum, bronchitis. November 26, 1918. Cough tightness across front of chest, short winded. General condition good, color and nutrition excellent. Voice a little hoarse. Chest shows scattered moist râles, but the breath sounds are otherwise clear and normal. September 1, 1918. Right upper chest is smaller than left, with slight dullness along right clavicle and down to third rib. Both apices are narrow, right more so than left. Breath sounds are harsh everywhere, with high-pitched musical râles, especially over both lower lobes posteriorly.

January 14, 1919. There is little sputum but considerable cough. There is dyspnea after moderate exertion; is easily fatigued. Few mucous clicks heardover right upper lobe posteriorly, expiration prolonged over both upper lobes in front. February 20, 1919. No T.B. in sputum on repeated examinations. There is cough with morning purulent sputum 3 oz. in 24 hours. There is dyspnea on moderate exertion, *e.g.* running 75 yards. The *x*-ray reveals extensive fibrosis throughout the chest, particularly marked on the right side. Along the course of the right vertical bronchus and extending out into the first and second interspace trunks on this side, there is considerable matting, small fibrotic nodules are frequent, and these extend far out into the periphery of the lung tissue. The left hilus is thickly studded with calcified nodules and the vertical bronchus shows considerable matting, and numerous calcified nodules along its course also. In the left hilus, however, are small bronchiectatic cavities. This is present in a less marked degree in the right hilus also.

Diagnosis: It is difficult to arrive at an accurate interpretation of these plates, but it is my opinion that a double process is represented here, that in the hilus being bronchiectasis, and that extending up into the apices and the interspace trunks, probably being an old tuberculous infection. There is no gross disease, and no very extensive localized lesion and no evidence of present activity.

Small localized saccular bronchiectasis in both lung roots and probably tuberculous involvement in the apices and vertical bronchi. Bronchitis and bronchiectasis with quiescent pulmonary tuberculosis.

CASE XXIV.—Pte. J. R. Age 30 years. Pleurisy left base, 1915, preceded by bronchitis. Chronic bronchitis, winters, 1916-1917. In hospital six months as tubercle of lung, as up patient with transient fever. No. T.B. in sputum. Working ability one-quarter.

July 14, 1918. General condition good. Loss of weight 8 per cent. More or less continuous cough, varies with posture ; sputum two ounces, odorless. Dyspnea on exertion. Pain left lower chest.

Physical examination shows a lessened movement of left chest with contraction in area fourth to seventh rib anterior and axillary, with marked dullness and loud bubbling consonating râles. Corresponding posterior area about angle of left scapula with dullness and coarse râles. A few crepitations about right nipple. Fingers and toes clubbed. *X*-ray shows unilateral localized saccular dilatation in left lower lobe with associated slight hilus shadows and heavy bronchial shadows. Left diaphragm blurred.

Diagnosis: Bronchiectasis left lower lobe.

CASE XXV.—Pte. B. Cough began June 14, 1916, day after gunshot wound of thigh. Returned to Canada, December, 1916, as chronic bronchitis. Readmitted Spadina Military Hospital, June 1, 1918. Severe cough, three ounces of purulent sputum. Fingers clubbed.

Physical examination shows dullness with signs of multiple small cavities, left lower lobe; some rhonchi over right lower lobe. P.M.I. displaced outward, no movement of left lower lung border. *X*-ray shows no movement left diaphragm, high, adherent. Hilus shadows heavy in the left lower lobe. Behind and outside heart shadow, heavy bronchial shadows rather flocculent with multiple dilatation of bronchioles. Heart much to left.

CASE XXVI.—Ethel M. Age 14 years. March 17, 1919. Cough from infancy, began at two weeks of age, aggravated by whooping cough at six months and two attacks of measles. Troublesome cough. Sputum 4 ounces daily, purulent, odorless, frequently blood-streaked. Nutrition good. Fingers slightly clubbed. P.M.I., fifth interspace outside nipple. Left chest moves little and upper lobe impaired. An area of dullness, right infrascapular. Uncertain and shifting râles and rhonchi throughout the chest. Sputum repeatedly negative to T.B. Tuberculin—no reaction. Under the *x*-rays the ribs appear horizontal. Dilatation of bronchi about right and left hilus, extending further on the right. General increased clearness of lung.

CASE XXVII.—H. B. Age 8 years. January 20, 1919. Cough for three years following measles and pneumonia. Several coughing spells daily with much sputum each time. Half cup 24 hours. Sputum yellow. No odor. Physical examination shows the child to be pale and thin. Fingers clubbed, cyanosed at tips. Left chest contracted. Shoulder and nipple low and left costal margin indrawn. Visible precordial pulsation third, fourth, and fifth space. Dullness to left of heart extending to axilla and left infrascapular with uncertain bubbling râles, not consonating. *X*-ray shows wide dilatation in bronchial tree, left lower lobe

laterally and anteriorly, left diaphragm high and left chest contracted. Some dilatation in right hilus. Tuberculin—no reaction.

Diagnosis: Bronchiectasis left lower lobe, slight about right hilus.

CASE XXVIII.—Lewis T. Age 8 years. March 6, 1919. Had whooping cough at five. Always delicate. Subject to bronchitis but in fair health until last June, when he had a bronchitis which has persisted. At times is less but does not clear. Late in February had influenza. He has severe vomiting spells every day for past week, result of severe cough. Sputum one-half cup daily.

Physical examination reveals a very thin and pale child. Fingers bulbous, tips cyanosed. Chest thin. Expansion poor at bases. P.M.I. diffuse in fifth space. A few scattered râles over lower front right and left posteriorly. Marked dullness left infrascapular with bronchial breathing and consonating bubbling râles. Right infrascapular, slight impairment of resonance with numerous non-consonating râles.

Diagnosis: Bronchiectasis of lower lobes, greater on left side. Tuberculin test negative.

CASE XXIX.—Florence W. Age 24 years. Admitted October, 1918, following serious hemoptysis. Had been at sanatorium one year for tuberculosis. Cough for three years following severe cold. Sputum gradually increased to two ounces daily, frequently pink in color, no odor, no tubercle bacilli found while in hospital and none during year at sanatorium. Fingers and toes clubbed. Slight reaction to tuberculin. Left lower chest moves slightly. Infrascapular dullness with limited area of high pitched bronchial breathing and consonating râles, also bubbling râles. *X*-ray shows numerous dilatations through left lower lobe, a few in right.

CASE XXX.—Joseph L. Age 31 years. January 23, 1919. Cough since March, 1915. Is positive had no sputum until two months ago when ill with "lung trouble." Cough has persisted, but the man has been at work since December, is losing weight, debility increasing, working in dusty occupation. Temperature normal. Lost eight pounds. Is thin. Coughs mostly night and morning with half cup of sputum.

Physical examination is negative. Sputum contains no tubercle bacilli. *X*-ray shows dilated bronchi about right hilus limited to larger divisions.

CASE XXXI.—Minnie M. Age 32 years. June 6, 1918. Cough since December, 1916. Pleurisy, 1917. Sputum increasing to ten ounces daily. In June, 1917, hemorrhage two drachms, August 2 ounces. August, 1918, four ounces, and began to develop unpleasant odor which still continues. Still has occasional hemoptysis, one ounce to a cupful often preceded by pink sputum. Odor now unpleasant. Repeatedly negative for T.B. Skin does not react to tuberculin.

Physical examination.—Lower border of right lung high, moves little. Numerous localized râles somewhat consonating, and tubular quality to breath sounds right infrascapular. Occasional râles left infrascapular with no change in breath sounds. *X*-ray shows numerous dilatations in bronchi of right lower lobe lying in dense pulmonary shadow. Slight dilatation of left lower bronchial divisions.

Diagnosis: Bronchiectasis, particularly right lower lobe.

CASE XXXII.—Madeline S. Ten years of age. January 29, 1919. Some cough for three years following pneumonia, aggravated by influenza October, 1918. Since then troublesome cough persists with ten ounces purulent sputum. Is pale, finger tips cyanosed and slightly clubbed.

Physical examination.—Right infrascapular area dull, as is axillary below fifth rib and the anterior part of lower lobe area; bubbling râles present in dull area. Diaphragm appears fixed. No reaction to tuberculin. *X*-ray shows right diaphragm high in its inner third with adhesions. Hilus shadows heavy in upper poles; lower left is hidden by pulmonary shadow which extends out beyond heart border, in this are seen dilated bronchial divisions. Some dilatation close to left hilus in lower lobe.

Diagnosis: Bronchiectasis with fibrosis of right lower lobe and basal pleural adhesions.

CASE XXXIII.—Frances B. 2½ years. February 26, 1919. Cough since measles six months ago, both day and night, loose, mucous, but does not expectorate. Mother thinks she swallows "a lot of phlegm." General condition good, no fever, does not react to tuberculin. There is an area of dulness with faint bronchial breathing and bubbling râles and rhonchi about inferior angle of right scapula. *X*-ray shows slight contraction of right chest, heavy hilus shadows right with some dilated bronchi in lower lobe. Some scattered peribronchial densities in left upper lobe.

Diagnosis: Bronchiectasis, right lower lobe.

CASE XXXIV.—Fred G. Age 8 years. Has had a chronic cough for five years. One previous admission to hospital for bronchitis, three years ago. Always a weak frail child. His mother has chronic bronchitis. June 1, 1919. Poorly developed, poorly nourished, appears delicate. Coughs often, single, loose. Fingers slightly clubbed. Chest expansion equal, resonance slightly diminished over right infrascapular. Showers of small râles in both lower lobes posteriorly, more intense on right. No reaction to tuberculin. No T.B. in sputum. *X*-ray shows multiple small saccular dilatations well out from hilus in right lower lobe, a few in left. Main divisions not dilated.

Diagnosis: Bronchiectasis of smaller bronchioles lower lobes, principally right.

CASE XXXV.—Arthur C. Age 12 years. Had cough since influenza, November, 1918. Admitted to hospital, April, 1919. Because of discharging ear with presence of diphtheria bacilli, was transferred to isolation hospital, re-admitted when clear. June 1, 1919. Yesterday coughed up two ounces bright red blood, sputum ordinarily two ounces, heavy purulent, occasionally stained with blood. Patient is well developed, well nourished, but very pale. Fingers and toes slightly clubbed. Temperature rises usually to 100° in the afternoon.

Physical examination reveals signs of high adherent right diaphragm with cavity signs and consonating râles about inferior angle right scapula, coarse râles and rhonchi general throughout right lower lobe. Little movement right lower chest, occasional rhonchi left lower lobe. Does not react to tuberculin. No T.B. in sputum. *X*-ray shows widely dilated right main bronchus and branches in lower lobes. Increased density of pulmonary shadows with high immobile right diaphragm.

Diagnosis: Bronchiectasis involving particularly larger divisions right lower lobe with old basal pleurisy.

CASE XXXVI.—J. P. T. Age 33 years. Cough in morning since pleurisy, 1908, recurring attacks of pneumonia since, always confined to left lower lobe. Sputum two ounces daily, purulent, rarely blood stained. June 9, 1919. Left chest much contracted, anteroposterior diameter two-thirds that of right, trachea passes behind inner end of left clavicle. P.M.I. fifth space outside nipple, little movement left chest. Harsh breathing above, marked dulness fifth rib to base axillary and posterior with cavity signs and bubbling râles. *X*-ray shows extensive fibrosis throughout left lung, particularly in lower lobe with widely dilated main bronchial branches. Mediastinum displaced much to the left, general contraction of left chest with kyphosis and marked scoliosis.

Diagnosis: Bronchiectasis, left, involving the larger branches, with fibrosis of left lung.

CASE XXXVII.—I. H., 23 years of age. Cough since childhood, sputum always free, purulent, rarely confined to bed but no day free from cough. Completed college course satisfactorily.

February, 1918. Sputum four ounces daily, purulent, no fever, general condition fair, fingers clubbed. In left lower lobe axillary and infrascapular, slight dulness with harsh breath sounds and many bubbling râles a few râles and rhonchi L.U.L. from second rib down to dull area. *X*-ray shows heavy bronchial shadowing general in lower lobes and left upper with dilatation of main trunks about left hilus, upper and lower, with involvement of smaller branches in lower lobe.

Diagnosis: Bronchiectasis about left hilus and in left lower lobe.

CASE XXXVIII.—R. C. Age 21 years. Cough each winter since childhood; in 1912-13-14 persisted through

summer, takes cold easily. First examination, March, 1913. April, 1915, general condition excellent. Good color. Troublesome cough. Sputum two ounces, purulent, no odor. Limited movement lower left chest with dulness lower axillary and infrascapular, distant bronchial breathing and many bubbling râles. March, 1919. Developed into a big strong young man. For past two years cough and sputum have been lessening but subject to increase at times in winter. Now has little and works steadily. Dulness has lessened. Left diaphragm moves little, no bronchial breathing in left lower lobe but a few râles present with cough. Fingers less clubbed. *X*-ray in 1913 showed heavy wide bronchi in lower lobes, greater in left.

Diagnosis: Bronchiectasis in left lower lobe bronchi, bronchitis lessening, almost recovered from symptoms.

CASE XXXIX.—S. A. M. 33 years. Cough for four years gradually increasing sputum at first mucoid, then muco-purulent and occasionally foul. After 1½ years brick-colored sputum appeared occasionally and during past year is more frequent. In latter part of 1918 had frank hemoptysis of two to four ounces, several times in a week, and again twice in 1919. Always rather delicate but at work steadily except during hemoptysis. March 12, 1919. Sputum about three ounces, frequently blood stained. No. T.B. at any time. Has been diagnosed tubercle of lung. Physical examination of chest, negative. *X*-ray shows dilated primary and secondary bronchi in both lower lobes.

CASE XL.—M. F. 33 years. Seen in consultation February, 1919, with influenzal pneumonia right lower lobe. In addition to the general involvement there were cavity signs about inferior angle of scapula with coarse consonating râles. Fingers clubbed. As a child he had chronic cough and at about eighteen years of age was told he had a bronchiectatic cavity in right lower lobe and that his symptoms might increase as he grew older. On the contrary, his symptoms gradually lessened and for some years he has been free from cough except for occasional bronchial colds.

Diagnosis.—Bronchiectasis with recovery from symptoms, the physical signs persisting.

The case histories give the bare outlines of onset, symptoms and physical findings. In some cases the original files were not available when the preparation of this paper was begun, and as a result a few are incomplete, being made up from short sketch notes. In all but CASE XL, *x*-ray plates were made, and in two others neither the plates nor their readings were available for this paper. Thirty-seven roentgenograms have been studied and most of these were stereoscopic.

Age.—In the series the age incidence has been from 2½ to 40 years, 7 were children and 33 were adults, of whom 25 were soldiers.

Cough.—In two children, cough was present four and six months respectively and in three soldiers for six months; in seven other adults and one child was present under two years and in four others under three years, and in the remainder from three years upward, there being one record each of 15, 16, 17, 18, and 19 years cough.

Onset.—In twenty of the series the onset of the cough was associated with a bronchitis which became chronic. In seven the onset was dated back to a pleurisy, though in three of these there was an associated bronchitis. In seven pneumonia appears to have been the factor, and in these seven, one had many recurring attacks and was a complication of measles, and one of influenza. Three others are definitely traced to influenza and one to measles. Three are the result of enemy gas. In three the onset is not clear.

Clubbing of fingers was noted in 22. It was possibly present in more.

Hemoptysis.—In twelve there was spitting of blood in quantity of a teaspoonful or more and in five of these the hemoptysis was large.

Odor.—An unpleasant odor was present in the sputum of only six. This is a minor point in diagnosis and if absent should not influence the clinician in his diagnosis. Stress is laid upon this symptom in the older text-books, but it is not to be looked for in a large proportion of cases where diagnosis is made early.

Amount of Sputum.—In children it is difficult to estimate quantity of sputum. In the adults it has usually been one to three ounces in twenty-four hours, in four the amount has been less than this and in two there was none—they had become symptom free though physical signs persisted. Three had four ounces, one six ounces and only one as much as ten ounces.

Physical Signs.—Physical signs which would localize the lesion were absent in seven cases, and in eight others were suggestive but insufficient to localize.

Previous Diagnosis.—This was usually chronic bronchitis, tubercle of lung, suspect tubercle of lung or clinical tuberculosis (T.B. not demonstrated). In two, dilatation was diagnosed and in two others mentioned as probable.

Tuberculin.—In thirteen of the fifteen civilian cases reported the intracutaneous test was applied. Of the thirteen, four gave a slight reaction and nine did not react. Six of the children were tested and none reacted.

Localization.—All were lower lobe or perhaps in some middle lobe cases. Many showed some upper lobe involvement. Last year I reported one upper lobe case but none has been met with in this series with the lesion principally in the upper lobe.

Conclusions.—Bronchiectasis is not a rare condition and will be frequently met with in a special chest clinic. It is to be differentiated in its early stages from bronchitis and tubercle of the lung, in its advanced stages from pulmonary abscess and tuberculous cavity.

Hemorrhage is frequent and may be slight or severe.

Repeated examinations of the sputum for tubercle bacilli must be undertaken. Given purulent sputum which on a series of examinations shows no acid fast bacilli, the diagnosis of tubercle of lung is not justifiable until other chronic respiratory diseases have been excluded.

Clubbing of the fingers and toes is a very suggestive symptom.

In differential diagnosis a careful clinical history and a study of the symptoms and physical signs will usually determine opinion but the stereoroentgenogram is invaluable.

Nutrition has been good in most of the cases and is of some assistance in differentiating from tuberculosis.

X-ray Findings.—The single plate is of value only in the diagnosis of dilatations of the main bronchi or their primary divisions, and is not always satisfactory here. For dilatation of the smaller divisions or in the presence of much peribronchial infiltration and pulmonary fibrosis the stereoroentgenogram is necessary. It is an invaluable aid in diagnosis.

11 SPADINA ROAD.

THE CLINICAL VALUE OF SYSTEMATIC HISTORY-TAKING IN GALL-BLADDER DISEASE;

WITH CORROBORATIVE SURGICAL FINDINGS IN A SERIES OF TWELVE ILLUSTRATIVE CASES.*

BY ALBERT M. CRANCE, M.D.,

BAY CITY, MICH.

FROM THE DEPARTMENT OF SURGICAL DIAGNOSIS, JONES CLINIC.

THE most important procedure toward the diagnosis of gall-bladder disease, including gallstones and stones in the common duct, is systematic history-taking. Much depends upon the type of history taken, however, and unless certain points are dwelt upon with considerable emphasis, the history is more apt to be misleading than it is helpful.

In order to take a careful gall-bladder history, there is one requirement of primary importance; that is, time. Very valuable data will be missed if attempts are made to hurry through the history, whereas, on the other hand, information of little value will often be interpreted as being of great importance. It is not necessary to listen to the patient tell his story, first because he will wander far away from the subject, and secondly because it uses valuable time and results in a general tangle of ideas as regards the case. More valuable information will be obtained if questions are asked the patient.

The most common complaint given by patients suffering from gall-bladder disease is "pain in the stomach," or "stomach trouble." A less common complaint is "pain in the right upper quadrant of the abdomen." And yet it is true that a huge number of these cases have gone on for many years with this complaint, and in most instances their symptoms have been treated rather than the actual cause of their trouble. This has been termed "snap-

TABLE SHOWING FORM OF HISTORY FOLLOWED, WITH FLUOROSCOPIC, X-RAY AND SURGICAL FINDINGS.

No.	Sex	Age	Complaint	Duration	Aggravated by Food	Vomiting.	History of Previous Attacks	Requiring Hypo.	Character of Pain.	Referred Pain.	History of Jaundice.
1	F	36	Pain in stomach.	15 yrs.	Yes. 2-3 hrs. after or immediately after meals.	No.	Yes.	No.	Sharp pain at times, epigastric region and at right costal margin.	No.	No.
2	F	37	Pain in pit of stomach	10 yrs.	No.	Yes.	Annually repeated attacks.	Yes.	Sharp pain at times in pit of stomach.	Right subscapular region.	With the attack 1 yr. ago.
3	F	54	Pain in stomach and nervousness.	7 yrs.	Usually after meals.	No.	More or less constant with some periodicity.	No.	Distress in epigastrium.	No.	No.
4	F	32	Pain in upper abdomen.	11 yrs.	Yes.	No.	Yes.	No.	Sharp pain at right costal margin thruout upper abdomen. Lately frequently and worse.	No.	No.
5	F	26	Pain in stomach and abdomen.	7 mos.	Not as a rule.	With each attack; brown bitter vomitus.	1st attack 7 mos. ago. Sharp pain in stomach, vomiting, chills with jaundice.	Yes.	Sudden sharp pain in epigastrium.	Right subscapular region.	Yes.
6	M	21	Pain in stomach beginning after meals lasting 1½ h.	1½ yr.	Yes.	No.	Continuous.	No.	Sharp pain in stomach immediately after eating lasting, 1½ hrs.	Lower left quadrant of abdomen.	No.
7	M	19	Pain in stomach.	4 mos.	Slightly.	No.	Continuous.	No.	Burning sensation in stomach; worse when walking.	Occasionally to right subscapular region.	None.
8	F	33	Stomach trouble anorexia.	10 yrs.	Yes.	No.	Yes.	No.	Occasional pain over gall-bladder.	Right subscapular region.	Yes, when 4 yrs. of age.
9	F	28	Pain in right abdomen.	2 yrs.	No, but aggravated by coughing.	No.	Yes.	No.	Sharp pain at times at right costal margin, aggravated by coughing.	No.	Since childhood, quite marked at times.
10	F	57	Pain in pit of stomach.	3 mos.	Yes.	Yes.	3 mos. ago.	Yes.	Sharp pain in pit of stomach.	Right subscapular region.	With first attack.
11	F	48	Pain in stomach piercing through to back.	2 yrs.	Yes. Warm drinks especially.	Not until a week ago—pain was so intense.	No.	No.	Constant pain, piercing through to back.	Both shoulders and arms to elbows; worse in right shoulder.	None.
12	M	59	Pain in stomach and liver trouble.	12 yrs.	Food eased at times.	Yes at times.	Not until 3 weeks ago.	No.	Dull pain in stomach and in right upper quadrant.	Right subscapular region and back.	None.

diagnosis," the results of which method are perfectly obvious.

On the other hand, regardless of the history, it is advisable to examine these patients with the fluoroscope as well as to make a careful study of their *x*-ray plates, in order that such conditions as gastric and duodenal ulcers, carcinoma and lues of the stomach may be found or eliminated, as the case may be. In a certain percentage of cases the *x*-ray has been of considerable help in making a diagnosis of gall-bladder conditions. Therefore, it is not my purpose to outrule the importance of either fluoroscopy or *x*-ray, but rather to emphasize the importance of correct history-taking.

I have tabulated a series of twelve consecutive cases observed at the Jones Clinic, in which cholecystectomy was done, either because of the presence of chronic cholecystitis or because of the presence of gallstones, to illustrate the clinical value of systematic history-taking. I particularly want to refer to the cases with the complaint of "pain in the stomach." Unless a systematic method of taking such histories is followed, a conclusion might very easily be drawn that would suggest the presence of gastric or duodenal ulcer, because there are so many symptoms common to each condition. (See table.)

Let us review the important points of value that are common to nearly all, as well as valuable toward a differential diagnosis.

1. First of all, the majority of the cases show the condition to be of long standing.

2. Several of the patients stated that the condition was aggravated by food, either immediately or two or three hours after meals. At this point, if we were to follow out an ulcer history, we could very easily obtain enough points to make a conclusion of ulcer. It shows the necessity of following out the gall-bladder history in a systematic way.

3. Vomiting has been common in those cases with a history of previous sudden and severe attacks.

TABLE SHOWING FORM OF HISTORY FOLLOWED—(*Continued*)

PRESENT JAUNDICE	PREVIOUS ABDOMINAL OPERATION.	BELCHING GAS.	PERIODICITY.	ABDOMINAL EXAMINATION.	DIAGNOSIS MADE PRIOR TO ANY LABORATORY TESTS.	FLUOROSCOPIC FINDINGS.	X-RAY DIAGNOSIS.	SURGICAL FINDINGS
None.	Appendectomy 1 yr. ago.	Yes.	Yes.	Tenderness throughout right abdomen; marked over gall-bladder.	Duodenal ulcer or cholecystitis.	Duodenal deformity.	Duodenal ulcer.	Gall-bladder large—Collapsed with difficulty. Chronic cholecystitis.
Slight.	None.	Yes.	Worse in the Fall.	Tenderness elicited only at ensiform.	Chronic cholecystitis.	Negative stomach and duodenum.	No opinion.	Chronic cholecystitis, gall-bladder full of pea-sized stones. Chronic appendicitis.
No.	Hysterectomy 12 yrs. ago.	Yes.	Yes.	Questionable mass in epigastrium. Tenderness over gall-bladder	Chronic cholecystitis with 10% chance of carcinoma of stomach.	Reflex spasm on greater curvature near pylorus. Duodenum filled easily.	Lesion of stomach.	Gall-bladder hard, white with appearance of fibroid tumor. Contained pus and full of stones. Ulcer of lesser curvature of stomach, suspicious of beginning carcinoma.
No.	Appendectomy 14 yrs. ago.	Yes.	Yes.	Slight tenderness at right costal margin.	Chronic cholecystitis.	Not made.	Not made.	A very large gall-bladder, chr. cholecystitis; filled with small stones. Stones in upper and lower portions of common duct.
Marked.	None.	Occasionally.	Slight attacks within 7 mos.	Tenderness over gall-bladder and appendix.	Chronic cholecystitis with gall-stones and stones in common duct. Chr. appendicitis.	Not made.	Not made.	Gall-bladder full of stones. 4 stones in common duct. Chr. appendicitis.
No.	None.	Yes.	Worse at times.	Tenderness in epigastrium and over gall-bladder.	Chronic cholecystitis or duodenal ulcer.	Small duodenum. Stomach neg.	Cap deformity. Duodenal ulcer.	Chr. cholecystitis with adhesions to duodenum. Chr. appendicitis.
No.	None.	Yes.	None.	No tenderness elicitable.	Chronic cholecystitis and appendicitis. possibly duodenal ulcer.	6-hr. meal in caecum. Stomach small with active peristalsis. Duodenum fills easily but not completely.	Slight suggestion of gastric lues.	Chr. cholecystitis and appendicitis.
No.	None.	Yes.	Yes'has gone 2 or 3 months without pain.	Negative.	Chronic cholecystitis with stones. Chr. appendicitis.	Stomach and duodenum negative.	Hyperperistalsis. Negative stomach and duodenum.	Cholecystitis. No stones. Gall-bladder was constricted 1 in. from its pelvis. Glands felt along common duct. Chr. appendicitis.
Slight.	None.	No.	No.	Tenderness high in right hypochondriac.	Cholecystitis.	Not made.	Not made.	Chronic cholecystitis and appendicitis. Fecolith in appendix.
Severe.	None.	Yes.	2nd attack.	Tenderness over gall-bladder.	Acute exacerbation, chronic cholecystitis with stones—also stones in common duct.	Not made.	Not made.	Chr. cholecystitis with gall-stones—4 stones in common duct. Carcinoma at head of pancreas.
None.	None.	Slight.	Worse in cold weather.	Questionable mass in epigastric region.	Chronic cholecystitis with stones.	Negative stomach and duodenum.	Negative.	Chr. cholecystitis, with stones There were two large ovoid stones one inch in length and several smaller ones.
None.	None.	Yes.	None.	Marked tenderness over gall-bladder.	Chronic cholecystitis.	Negative stomach and duodenum.	Negative stomach and duodenum.	Chronic cholecystitis, with adhesions between gall-bladder and duodenum. Chronic appendicitis. A small haemangioma cavernosum on the edge of the liver.

4. A history of previous severe attacks, especially if a hypodermic injection was required at that time, is indicative of gallstones. If we add to this a history of previous jaundice, there is a stronger possibility that stones are present in the common duct. Unless there is jaundice present at the time of examination, there are apparently no other means of diagnosing common duct stones.

5. The character of the pain is exceedingly important. Sharp pain in the right hypochondriac or epigastric region is more indicative of stones, whereas dull pain in that region is more indicative of chronic cholecystitis.

6. Referred pain, especially to the right subscapular region, seems more prevalent in cases with stones, although it can be present to a marked degree in cases of chronic cholecystitis.

7. A symptom common to nearly all in this series is the belching of gas. This one symptom accounts for a lot of serious consequences. For example, with a complaint of stomach trouble and the belching of gas, the snap-diagnosis is too frequently made of "chronic indigestion," "inflammation of the bowels," or the like. The patient is treated with some remedy that apparently may relieve him, or tide him over until the symptoms return again, or possibly several times. In one of the cases herein mentioned, the patient was so treated for a period of 12 years, and yet he had every symptom of the conditions found at the operating table. Is it not perfectly obvious that more careful history-taking is absolutely essential in the diagnosis of these cases?

8. Periodicity, so characteristic a symptom of duodenal ulcer, might be mentioned as being more or less common in gall-bladder disease also. However, in gall-bladder histories, the statements of previous severe attacks is of considerably more importance than periodicity.

In the table I have also made mention of the abdominal examination. In all but two of the cases, definite tenderness could be elicited in the region of the gall-bladder. In two of the cases, the presence of a mass was suspected. I bring out this point simply to illustrate how this physical finding compares with the histories, and how valuable in the way of a diagnosis it is.

The fluoroscopic and *x*-ray findings are mentioned because in a certain percentage of gall-bladder cases these findings are valuable. In addition, both of these procedures have considerable value, as regards the elimination of other possible conditions.

The diagnosis given is the "tentative diagnosis" that was set down after the history and complete physical examination were finished, previous to any laboratory tests or *x*-ray observations.

Summary.—These few cases illustrate the value of systematic history-taking in the diagnosis of gall-bladder disease. The valuable relation between the history and abdominal physical findings is also well shown. In the order of their importance, we could mention the following points as being more or less diagnostic: History of long standing stomach trouble, or pain in the right upper quadrant of the abdomen; previous attacks of sharp pain in the right upper quadrant of the abdomen associated with or without jaundice; history of such intense pain that a hypodermic injection was required (stones); pain referred to the right shoulder, possibly to both shoulders, or downward across the abdomen; feeling of distress, or aggravation of the symptoms after meals, associated with the belching of gas.

The physical finding of paramount importance is the presence of tenderness in the region of the gall-bladder. This can easily be elicited upon deep palpation. If tenderness be present, comparison with the opposite side should always be made. The absence of tenderness on the left side in such cases is a very valuable sign to add to the diagnostic points of gall-bladder disease.

In conclusion, therefore, it should be emphasized that gall-bladder histories require time, as well as a systematic method of taking them. By following a routine form in taking histories in such cases, the making of a diagnosis otherwise difficult will be greatly simplified.

A STUDY OF THE NATURAL SARATOGA-NAUHEIM BATHS AT SARATOGA SPRINGS, N. Y.*

By JOHN FREEMAN HUMPHREY, M.D.,
SARATOGA SPRINGS, N. Y.
ATTENDING PHYSICIAN TO SARATOGA HOSPITAL.

In presenting a study of the natural Nauheim baths, as made in this country, I appreciate the fact that I am entering upon the discussion of an entirely new subject of medical interest, the practical value of these baths, as a therapeutic measure, having impressed but few of the profession. The reason for this is the fact that the data available have not been sufficient to present the subject in a comprehensive, practical form with regard to just what these baths are able to do and the type of cases to which they are applicable.

The natural Nauheim baths at Bad Nauheim, Germany, have been used for many years with success in chronic heart diseases by those noted internists, Gradel, August and Theodore Schott, and their confreres, who, by their continued study of the compensatory changes presenting in individual cases, made application of these baths with a rational regime to which the profession of the world has been attracted. The early work of these physicians was entirely with the myocardial diseases with hypotension, superinduced by valvular diseases and a progressive decompensation, for which they found the Nauheim baths a positive benefit; the continued prescribing of the baths led to a wider field of application. It is only within the past two decades that the Nauheim baths have become known as an important therapeutic adjunct in the treatment of the myocardial and vascular changes incident to many forms of chronic disease; it is also within that period that the profession of all Europe and many internists in this country began to advise their patients to make pilgrimages to Bad Nauheim that they might receive the benefit of these baths under the direction of the physicians who had become famed in their application.

It is within the past ten years, when the baths

*Read before the Medical Association of the Greater City of New York, May 17, 1920.

at Bad Nauheim were no longer available, that the mineral waters at Saratoga Springs have been made the subject of intense study as to the possibility that their mineral salts might be productive of results equal to those springs at the European Spa. The discovery of an unusual content of carbonic acid gas and radium, intensifying the therapeutic value of the salts and reproducing an ideal Nauheim bath, has resulted. This study of the baths at Saratoga Springs has now continued over a period of ten years, resulting in the establishment of a comprehensive regime, surrounding the baths with special instructions as to diet, rest, exercise and taking the waters, and in addition, sufficient restrictions have been placed about the patients to attain the best results. The success of this regime could not have been achieved without recording a careful history and making a complete physical examination in each case, especially ascertaining the changes in the heart and vascular system, the determining factors in the results to be attained.

The physiological action of the natural Saratoga-Nauheim bath is exhibited as soon as the patient is immersed in the bath, by the collection of many layers of bubbles of carbonic acid gas over the entire body, which, coupled with the large percentage of natural mineral salts, creates a dilatation of all the superficial blood vessels, made evident by the immediate slowing of the pulse and the decided flushing of the skin.

This retardation of the pulse continues during the entire bath, as exhibited by the pulse recorded before, during and after each bath, which shows a decline of six to twelve beats to the minute. Correspondent with this fact is the very deep reddening of the skin and the decided tendency to perspiration, even in a bath of an indifferent temperature of 98° F. The continued slowing of the pulse during the entire bath is significant that the dilatation of the arterioles extends more deeply than the superficial circulation, reaching the deeper vessels, as is evidenced by the progressive retarding of the pulse, which has slowed the entire circulation; the blood of the deeper vessels passes into the dilated arterioles, thereby relieving the work of the myocardium and left heart, with a resulting lengthened diastole, creating a longer rest to the heart in its cycle and an opportunity to recover its nerve function.

The increased length of the diastolic pause is the most potent result attained by the Nauheim bath, this pause being extended from one-tenth to one-fifth of each minute during the bath and retaining this control for many hours, thus affording to the weakened myocardium and its nerve function an extension of time by which to achieve an adequate compensation.

The retardation of the pulse, coupled with improved metabolism and the recovery of compensation, are the determining objects to be attained in a course of Saratoga-Nauheim baths, as some of the patients for whom these baths are prescribed present at examination a high tension regular pulse, while others present a weakened impulse, a result of a long continued hypertension or an acute infection with a resulting hypotension. Another type of cases, superinduced by one of the chronic diseases, can be influenced only up to a certain point, while others, induced by a functional toxemia, respond in the shortest possible time, in both conditions the Nauheim bath achieving beneficial results, in the one case a general relief to the heart and circulation, in the other a complete cure.

One of the most gratifying effects of the Nauheim bath and one which is very early experienced by the patient is the feeling of exhilaration resulting from the adjusted circulation and improved matabolism, stimulating the nerve centers by the action of the mineral salts, carbon dioxide gas and radium content, thereby effecting a more active elimination of the products of any toxemia and stimulating an active assimilation.

The Saratoga-Nauheim bath is prescribed primarily for its effect upon the heart and circulation; but it is a clinical observation that if the nerve centers are not affected, the metabolism improved, toxic products completely eliminated, and the active initiative in the patient returned, the intent of the bath is not attained. The regime prescribed must have an effect on not only the hypertension and hypotension, but also the diseases, either functional or chronic, by which they are superinduced.

It will be seen that the regime prescribed for the heart must be applicable also in part to the associated diseases; the treatment and improvement must progress simultaneously in order that the best results may be achieved.

A course of treatment with the Saratoga-Nauheim baths consists of from twenty-one to thirty baths, extending over a period of four to six weeks, the number and frequency being suggested by the result of the examination of the patient. The baths are prescribed in series of one to three baths, followed by a rest day, at which time the regime is continued except the bath. On each rest day a complete examination is made with a view of noting progress, making any correction in the regime that may be necessary, and giving instructions for the succeeding series.

The mineral water used for the baths carries fifty-five per cent, of carbon dioxide gas, which is generally continued through the entire course of baths.

The length of the baths as prescribed for the Nauheim patients varies progressively from seven minutes up to twenty or twenty-five minutes, as may be suggested by the conditions presenting in each individual case.

The temperature is the most important detail of the Nauheim bath and the most difficult of adjustment in each case. In the hypotension patients, who are always affected through their nervous system and bear the cool bath well, it may be as low as 88 or even 86 degrees F., with most beneficial results, while in the hypertension cases the temperatures are most effective and serve a greater degree of comfort to the patient when directed upward, but never above 99 degrees F., as the higher temperatures prove enervating.

A rest of one hour is advised after each bath in order that the circulation may be adjusted and the physiological action of the bath may be amplified; if sleep is obtained so much advantage is gained in exhilarating composure to the nervous system, which may in the hypotension pa-

tients, be followed by a light massage at first and later by gymnastic exercises, as prescribed in the individual case.

The gymnastic exercises conceived by Schott and also the graduated grade walks suggested by Oertel, as an adjunct to the baths, have proved of the greatest benefit to patients affected with a myocardial relaxation.

The contra indications to prescribing the Nauheim baths are: decompensation associated with an irregular, intermitting heart action with tachycardia; general anarsca or even a considerable edema of the limbs with some ascitos; severe or repeated attacks of angina pectoris, or a dilatation of the left heart. However, some of these patients, after a long rest, are sufficiently improved that the baths prove of great benefit and become the means of a partial recovery.

The after cure is the continuation of the active cure at to diet, rest, exercise and taking the waters, either at the Spa, in the mountains or at the seashore, allowing the system to adjust itself after pursuing the regime. The patient must be advised with the same precision as to just how strenuous and also how quiet he may be, as for his original treatment. It is my experience that the patient who follows instructions as to his after cure, accumulates as much improvement as during the routine of the curative regime.

The patient with a low systolic tension is advised to follow the bath regime by a stay at the seashore, where he may participate moderately in ocean bathing, cool sprays and baths, but should refrain from taking hot baths of any kind or any active exercise, as tennis, running or jumping; he may walk and take exercises, also play golf moderately a part of each day.

The hypertension patient may go to the seashore but better inland or in the mountains—not high, taking moderate exercise, preferably golf, one hour at a time twice daily. Patients who have been the subjects of a constant arterial tension above 200 mm. of mercury, systolic, require a second course of treatment each year, that the cardiovascular tension and metabolism may be maintained at a more even ratio, and with less strain upon the myocardium and gastro-intestinal tract.

In all cases the regime that has been pursued during the treatment was prescribed in part for the disease with which the patient is affected, hence it should become to him the continued regime of his future living.

In the preparation of this paper I have utilized the clinical observations and tabulated histories of four hundred and six patients, for whom it has been my pleasure to advise a regime, including the natural Nauheim baths, the results of which have been of such decided benefit to patients and have impressed me with a deeper appreciation of the value of one of the most important therapeutic assets of which this country can boast—the Saratoga mineral waters and baths.

The series of cases that came under my observation during the past five years includes two in 1915, eighteen in 1916, fifty-three in 1917, one hundred and two in 1918 and two hundred and thirty-one in 1919, exhibiting the rapid development of the work as soon as a rational regime was established and the attendants could be trained to appreciate the importance of each detail of the bath.

These patients represented 137 males and 269 females, 148 of whom recorded a low arterial tension and 258 a high systolic pressure, reflected from the many diseases and infections with which these patients were affected.

Hypotension cases by ages:

10-20,	20-30,	30-40,	40-50,	50-60,	60-70,	70-80,
2	5	28	57	46	16	4

Hypertension cases by ages:

0	6	33	71	105	35	8

The etiological factors of hypotension were found in the anaemias, nerve exhaustion, valvular disease, and the toxaemias of la grippe, influenza, malaria and auto-intoxication, each proving a debilitating factor in the patients, the majority of whom had an associated anaemia.

The cases of low systolic pressure exhibit a debility out of proportion to their arterial tension; not that their pulse pressure is so great, but it is the reflection of the rheumatism, nephritis, valvular disease of the heart, diabetes, biliary disease, or gastric or duodenal catarrh, with which the patient is affected.

The most serious cases are those of myocardial decompensation with hypertrophy, which predominate the whole number of hypotension cases, some of whom present a low tension, while others are only moderately low or even what might be considered normal, but for the irregular, intermitting heart action with weak impulse at the apex, which is significant of very little myocardial recuperative power. The regime prescribed for these patients is rest in bed for two or more weeks, after which a bath each alternate day or with two days interval, before the succeeding bath, which is prescribed only after a complete examination, this careful regime being continued throughout the entire course.

It often occurs that these patients are business men or women or those whose duties necessitate close application; it is these patients who, having pursued a course of Nauheim baths and returned to their duties, are apt to exceed their limit of compensation and soon have undone all that had been accomplished, resulting in a relapse of an irreparable decompensation, acute dilitation or sudden collapse.

The lowest systolic pressure recorded was 70 mm. of mercury, and the greatest gains recorded during a course of the baths was 52 mm., the average gains obtained being from 15 to 30 mm., while in two cases no gain was obtained in a single course of 21 baths. It will be seen that of 148 patients recording low arterial tension, all but two of that number were benefited; in less than two per cent. of all treatments improvement was not possible.

Hypertension in the young is significant of a disturbed metabolism and assimilation, which can be corrected by a proper diet, free catharsis and the elimination of all toxic products. In middle life it is not only the result of a toxamia but also the initial stages of an arteriosclerosis coincident with one of the chronic diseases not fully defined

in some patients, while in others well developed in symptoms and pathology.

In the later decades of life we find these diseases fully developed, and the patients seeking relief from vertigo, insomnia, debility, and a variety of nervous symptoms, trying to find at different spas a regime that will procure for them a comfortable life.

In the group of cases of the type of hypertension, numbering 258 cases, 72 recorded a tension of 200 mm. systolic, or more, and nine of these patients had a tension of 250 mm. to 300 mm. systolic. These patients responded with great satisfaction, with the exception of five; these receded only 10 mm. to 15 mm. during their entire course of baths, while all the other patients responded from 20 to 60 mm. systolic.

In several patients for whom I had prescribed three or four years consecutively, I found that the pressure was reduced a little lower each year, although receding between each course, did not approach the highest recording point of the previous course of baths.

The dietetic regime in these cases, and especially in the higher registering cases, is of the greatest importance, the food prescribed must be less than the amount the digestion can take care of in the individual for whom it is prescribed. The real import is that intestinal fermentation must be reduced to a minimum, as all toxic processes affect the blood pressure, especially in patients having a systolic pressure above 200 mm.

The results that are attained by a course of the natural Nauheim baths are not entirely defined in the improvement achieved by the course of baths and the regime by which they are surrounded; but involve frequent examinations of and conferences with the patients, impressing them with the importance of each detail of the treatment, which really consists in establishing a regime of living for themselves as regards diet, rest and exercise as applied to their individual disease.

Summary of Indications.—The natural Nauheim baths are applicable to:

1. All chronic diseases having a high or low blood pressure, prescribed with a regime for that disease.

2. All diseases of the heart with hypertrophy and decompensation, without tachycardia or dyspnea.

3. Patients with an irregular and intermitting heart action, without tachycardia or dyspnea, or, with very little. In these cases the action is regulated, intermissions lessened, and hypertrophy diminished.

4. Patients with decompensation after sixty. Metabolism and assimiliation are improved, arterial tension relieved, and the myocardium strengthened.

5. Patients with low pressure from any cause. Metabolism and the debility, myocardial relaxation, and anemia are improved, which in turn elevates the blood pressure.

It is a clinical observation that with the improvement of the systolic tension the wide divergence of the diastolic tension, if any, is diminished coincidentally, demonstrating a normal reaction from the baths.

58 PHILA STREET.

PROPOSED VEGETABLE DRUG DELETIONS.*

BY A. RICHARD BLISS, JR., PHAR.D., M.D.,

ATLANTA, GA.

PROFESSOR OF PHARMACOLOGY, SCHOOL OF MEDICINE, EMORY UNIVERSITY.

IN the preface to the second edition of "Useful Drugs"† we find the following statements: "It has long been recognized that the multiplicity of drugs and preparations of drugs presented to the attention of the medical profession is an evil. Leaving out of account the articles described in the N. F. and the vast number described in dispensatories and similar unofficial compilations, the number of drugs and preparations described in the Pharmacopœia alone is far too large for intelligent practical use. *Of even greater importance is the well-known fact that a considerable proportion of Pharmacopœial drugs and preparations are superflous or worthless.* Repeated attempts to eliminate such articles from the Pharmacopœia have failed because they have uniformly encountered the objection that articles or preparations are used by some physicians and therefore should be recognized and authoritatively defined."

In accordance with the general trend of medical progress less and less attention and space in the medical school curriculum are being given to those drugs and preparations that are looked upon by medical authorities as being of minor importance, questionable utility, and doubtful reliability. Some of the latest editions of standard, recognized textbooks have gone further by absolutely omitting the greater proportion of such agents. Most of us will doubtless agree that the host of substances, good, bad, and indifferent, that were introduced to us in the college courses in Materia Medica, Pharmacognosy, etc., because of their very number, materially affected our interest in the subjects and led to considerable confusion and discouragement. This has been true not only in the college of medicine, but particularly in the pharmacy college. A movement to restrict the instruction in Materia Medica in the medical schools and the examinations in Materia Medica by State Medical Examining Boards to the more important drugs was initiated by the Council on Medical Education of the American Medical Association and the Confederation of State Examining and Licensing Boards. After numerous conferences with the State Examining Boards, professors of Materia Medica, deans of medical schools, and other members of the medical and pharmaceutical professions, the Council on Pharmacy and Chemistry of the A. M. A., following a thorough and careful sifting process, published "A Handbook of Useful Drugs," which is now being used as the basis of instruction in practically every Department of Pharmacology of the medical schools, and is also being used by the large majority of State Medical Examining Boards as the basis of examinations in Materia Medica and Therapeutics. The first edition appeared in 1913 and ushered in a long looked for and thoroughly welcome change in the scope of teaching in this par-

*Presented before the Scientific Section of the meeting of the American Pharmaceutical Association and of the U. S. Pharmacopœia Revision Convention in Washington, D. C., May, 1920.

†Press of the American Medical Association, Chicago.

ticular branch of medical science. Although practically every medical school and the large majority of State Medical Examining Boards are heartily cooperating in this work, it is doubtless a fact that the larger number of our schools of pharmacy are still clinging, for some reason or other, to the old method of trying to cram the pharmacy student full of information concerning every known member of the Materia Medica regardless of its usefulness or uselessness in the treatment of disease, regardless of whether or not it is being used by the medical profession.

Why waste valuable time and energy on pyrethrum, mezereum, xanthoxlyum, matricaria, etc., of the U. S. P., and asclepias, papaveris fructus, trifolium, verbena, echinacea, and a host of others of the N. F.? Why assist, by including these substances among the drugs taken up in the courses of the pharmacy school, in attempts to retain or to introduce such substances into the U. S. P.? Why encourage movements to introduce as many substances as possible, including socalled "household remedies," insect powders and other substances infrequently used as medicines, foods, reagents, etc., simply to have official and legal standards for the same? By taking part in such movements, intentionally or unintentionally, one assists in promoting still further departure from the original idea of the Pharmacopœia. A Pharmacopœia, we are taught, is a book which defines and standardizes *certain* drugs and preparations, and whose aim is to establish definiteness for a *selected number of those substances extensively used and recognized as possessing real worth in the treatment of disease by the physician.* The U. S. Pharmacopœia was founded by the medical profession, and was at first an *exclusive physician's Pharmacopœia.* Since 1840, however, the revisions have come more and more under the control of the pharmacist, and the work is gradually becoming a manufacturer's book of specifications and standards, and less and less of a guide to the medicinal agents prescribed by the medical profession.

Why defend the presence in or the introduction into the Pharmacopœia of substances which have been proven to be of no real value in the treatment of disease by saying that they are used by some physicians and therefore should be recognized? The real worth, the absolute value of a substance as a medical agent, should be proved, such proof recognized, and the real practical value further proved by extensive use before it is admitted to the U. S. P., and all substances now in the Pharmacopœia that do not meet these requirements should be deleted. Put them in the N. F. or elsewhere if you please, but get them out of the U. S. P. and keep them out. The writer ventures to state that unless the requirements for admission to the N. F. are made somewhat more stringent, this valuable work will gradually become the dumping ground for discarded members of the Materia Medica and slowly lose its prestige.

The approach of the U. S. P. Convention with that part of the program devoted to the subject of deletions prompted the writer to attempt to secure the opinions of the members of the medical profession in the city of Atlanta concerning one phase of this important work—Vegetable Drug Deletions. Accordingly a list of 121 U. S. P. vegetable drugs (excluding active principles like the alkaloids, glucosides, etc.) was compiled and mailed to the entire medical profession of Atlanta with the request that each man study the list and then strike out those drugs that he believed it would be wise to drop from the U. S. P., giving, in each case, very, very briefly his reasons for such recommendation. It is hoped that others may carry out a similar study of the vegetable drugs in other sections and also that the chemicals of the U. S. P. may be taken up in the same fashion. A study of the prescription files of the retail pharmacies of Atlanta was also begun in order to determine what substances are actually being prescribed by the medical profession of this city. The prescription data, although incomplete, are, nevertheless, too bulky to digest and to condense at this time. It will, therefore, be completed at a later date and used as the basis of another paper. The State of Georgia has a population of about 3,000,000, with a total of about 3,442 physicians. The city of Atlanta has a population of approximately 300,000 and a total of 513 physicians. The medical schools of practically every section of the country are represented by these men. Of the 513 physicians, 387 responded to the letter sent them. Therefore, the results of the communication represent the opinions of something over 75 per cent. of the medical profession of Atlanta.

Data Secured.

The replies show that the only U. S. P. vegetable drugs concerning which there is absolute unaminity of opinion are:

1. Aloes,
2. Asafetida,
3. Aspidium,
4. Balsam of Peru,
5. Balsam of Tolu,
6. Belladonna Leaves,
7. Belladonna Root,†
8. Capsicum,
9. Cascara Sagrada,
10. Cinchona,
11. Digitalis,
12. Ergot,
13. Gentian,
14. Glycyrrhiza,
15. Hydrastis,
16. Hyoscyamus,
17. Ipecac,
18. Jalap,
19. Linseed,
20. Lobelia,
21. Nux Vomica,
22. Opium,
23. Physostigma,
24. Pilocarpus,
25. Podophyllum,
26. Rhubarb,
27. Senna,
28. Black Mustard,
29. Veratrum Viride,
30. Ginger.

†Several suggested that the leaves alone would do.

Not one of the 387 who replied recommended the deletion of any of these thirty drugs listed above.

The following table gives the list of drugs along with the percentage of the 387 Atlanta physicians that advised deletion in each case.† The foregoing thirty drugs are omitted from the list:

Acacia	10	*Aconite*	11
Agar-Agar	12	Althæa	73
Sweet Almond	45	*Starch*	10
Anise	29	Arnica	34
Aspidosperma	52	Bitter Orange Peel	40
Sweet Orange Peel	20	*Benzoin*	10
Buchu	23	Gamboge	25
Calumba	50	*Camphor*	2
Cannabis	52	Cubeb	24
Caraway	50	Eriodictyon	63
Cardamom Seed	28	Fennel	42
Chondrus	63	Nutgall	24
Cimicifuga	37	Gelsemium	10
Cinnamon	13	Grindelia	26
Colchicum Seed	8	Guarana	55
Copaiba	13	Kino	55
Clove	18	Lactucarium	68
Chrysarobin	13	Lycopodium	23
Red Cinchona	13	Manna	60
Colchicum Corm	26	*Peppermint*	10
Colocynth	8	Mezereum	76
Coriander	60	Nutmeg	26
Elaterin	13	Parsley Fruit	60
Eucalyptus	8	*Tar*	10

Frangula	60	Pyrethrum	63
Gambir	60	Rosin	30
Pomegranate	24	Sabal	50
Guaiac	13	Red Saunders	63
Humulus	52	Sassafras	61
Lemon Peel	25	*Squill*	8
Malt	23	Serpentaria	50
Matricaria	70	Spigelia	37
Spearmint	23	Stillingia	32
Musk	60	*Stramonium*	8
Myrrh	10	Storax	55
Pepo	37	Taraxacum	32
Pepper	10	Triticum	42
Wild Cherry	8	Uva Ursi	37
Quassia	23	Viburnum Prunifolium	37
Red Rose	61	*Strophanthus*	10
Sanguinaria	50	Sumbul	61
Sarsaparilla	40	*Tragacanth*	20
Scammony Root	63	Elm	50
Senega	19	*Valerian*	16
White Mustard	10	Xanthoxylum	61
Staphisagria	40		

†The drugs printed in Italics are found in "Useful Drugs." The percentages printed in Italics include 50 per cent. and above.

From the table it will be seen that 50 per cent. or more of the Atlanta physicians favor deleting the following drugs:

1. Althaea (73%)
2. Aspidosperma (52%)
3. Calumba (50%)
4. Cannabis (52%)
5. Caraway (50%)
6. Chondrus (63%)
7. Coriander (60%)
8. Eriodictyon (63%)
9. Frangula (60%)
10. Gambir (60%)
11. Guarana (55%)
12. Humulus (52%)
13. Kino (55%)
14. Lactucarium (68%)
15. Manna (60%)
16. Matricaria (70%)
17. Mezereum (76%)
18. Musk (60%)
19. Parsley Fruit (60%)
20. Pyrethrum (63%)
21. *Red Rose* (61%)
22. Sabal, (50%)
23. Sanguinaria (50%)
24. Red Saunders (63%)
25. Sassafras (61%)
26. Scammony Root (63%)
27. Serpentaria (50%)
28. Storax (55%)
29. Sumbul (61%)
30. Elm (50%)
31. Xanthoxylum (61%)

Here, then, are thirty-one vegetable drugs that from 50 per cent. to 76 per cent. of a representative body of physicians advise deleting from the U. S. P. Among the brief reasons given are "inert," "useless," "limited utility," "obsolete," "worthless," "never used," "questionable value," "no advantages over other U. S. P. drugs of similar activity," "preparations unreliable and not uniform." It is interesting to note that of the thirty-one drugs, but one (red rose) is found in "Useful Drugs." It is also of interest to note that, with the exception of red rose, the percentage of physicians advising the deletions of other "Useful Drugs" was very low, camphor being lowest with but 2 per cent. favoring its deletion, and cardamon next highest to red rose with 28 per cent. The remaining ones run close to 10 per cent.

There is not a single drug in the above list of thirty-one proposed for deletion by 50 per cent. or more of the Atlanta men that possesses any medicinal actions or virtues which demand its presence in the U. S. P. and recognition as an important medicinal agent. There is not a single member of this list possessing any useful physiological action that is not also possessed by one or more of the remaining members of the U. S. P. There is not a member of this group possessing any particular redeeming virtues that demand its recognition; therefore, why retain them?

Comments and Conclusions.—In making the few comments and drawing the conclusions which follow, the writer has tried to keep in mind the original and supposedly present objects of the Pharmacopœia, and trusts his readers will consider them from the same standpoint. No attempt will be made to comment on all of the drugs proposed for deletion, attention being given only to those about which there is a fair degree of unanimity of opinion along with a comment or two concerning a few drugs the writer believes should be included in the list of thirty-one drugs referred to above.

It was rather surprising that a greater number did not advise deleting:

1. *Aconite*, the use of which is constantly diminishing, because the dangers attending its depressant action on the heart make it a rather undesirable agent to be used as a cardiac depressant. Only 11 per cent. advocated its deletion.

2. *Squill*, a drug rather carelessly used as an expectorant in numerous "stock mixtures" and "cough remedies" as well as in prescriptions. It has physiological actions that very closely resemble those of digitalis, although it is true that the emetic action is more pronounced. However, since we have other nauseating expectorants, like ipecac, for example, with less undesirable side actions, it seems unwise to use squill, which affects the heart so powerfully. The writer is confident that the deletion of squill will mean a loss to nobody. But 8 per cent advised its deletion, although prescription files show that it is gradually falling into disuse.

3. Pepo, a drug once used as an anthelmintic, but which has been proved to be absolutely worthless. Thirty-seven per cent. advised its deletion.

4. Gelsemium, a drug looked upon by practically all authorities as a peripheral depressant of no great medicinal importance. Only 10 per cent. advocated dropping it from the U. S. P.

Very briefly, then, the thirty-one drugs listed above as worthy of being deleted from the U. S. P. might well be dropped in the Tenth Decennial Revision for the reasons there stated.

In addition to these thirty-one, it is the writer's firm belief that the following might also be dropped since they, too, possess no redeeming properties or virtues that entitle them to consideration as "important, extensively used, valuable, therapeutic agents":

Aconite (11 per cent.), Agar-Agar (12 per cent.), Arnica (34 per cent.), Buchu, (23 per cent.), Sweet Almond (45 per cent.), Cimicifuga (37 per cent.), Gamboge (25 per cent., Fennel (42 per cent.), Gelsemium (10 per cent.), Grindelia (26 per cent.), Guaiac (13 per cent.), Tar (10 per cent.), Quassia (23 per cent.), Pepo (37 per cent.), Sarsaparilla (40 per cent.), Spigelia (37 per cent.), Stillingia (32 per cent.), Pepper (10 per cent.), Taraxacum (37 per cent.), Triticum (37 per cent.), Viburnum Prunifolium (37 per cent.), and Uva Ursi (37 per cent.).

It may be desirable in the cases of the aromatic oil drugs, such as anise seed, orange peel, caraway, clove, cinnamon, coriander, eucalyptus, lemon peel, peppermint, spearmint, nutmeg, and others, to delete the crude drugs and to retain the volatile oils, since the latter are the constituents which are really desired and actually employed in prescription work.

A further study of this subject in other sections will most likely disclose the fact that there is general unanimity of opinion concerning the drugs included in the list of thirty-one above, recommended by Atlanta physicians as worthy candidates for dismissal, and possibly also add several more drugs to the deletion list.

MAJESTIC HOTEL.

THE PROBLEM OF THE EFFICACY OF TOPICAL APPLICATIONS OF METHYLENE-BLUE IN FEMALE GONORRHEA.

By W. A. NEWMAN DORLAND, A.M., M.D., F.A.C.S.,
CHICAGO, ILL.
PROFESSOR OF GYNECOLOGY, POST-GRADUATE MEDICAL SCHOOL.

CONSIDERABLE interest, with coincidental friendly controversy, has been aroused by the advocacy of methylene-blue, in a 1 per cent. aqueous solution, in the treatment of gonorrheal involvement of the lower genito-urinary tract of women. The claims upon which this microbicidal remedy has been advanced as the best local treatment as yet proposed for this malady are as follows:

1. It has a powerful gonococcocidal action, being efficient in strengths of 1 to 250,000.

2. It is nonirritating to the tissues and, on the contrary, has a decided local analgesic effect.

3. It is followed by marked clinical relief of the symptoms complained of by the patients, includin gthe burning on micturition, vaginal and vulvar soreness, and the discharge. This improvement, in most of the cases, is noted in from 36 to 48 hours after the first application.

4. There is a rapid decline in the number of gonococci with their total disapperaance, on repeated examinations, after from six to twelve applications of the blue.

5. If there is no reinfection by uncleanly intercourse the germs do not reappear in the secretions of the cervical canal after weeks of non-treatment. It is, therefore, believed to be legitimate to claim a cure in those cases in which this condition has been brought about.

6. The clinical results obtained by the blue method are greatly superior to those following the usual methods adopted in gynecological clinics and in private practice.

The claims advanced by those who question the value of the method are as follows:

1. Practically, the disease, once having invaded the deeper tissues of the urethra and cervical and uterine canals, is incurable by topical applications. Given time, however, the disease will gradually cure itself after weeks, months, or even many years.

2. As yet no scientific proofs have been adduced in support of the blue method, but only claims based on clinical results.

3. If it be so efficacious in the genital tract of women, why will it not be useful also in that of men? Gonococci are the same wherever located.

4. Methylene-blue was tried as a gonococcocide two decades ago and abandoned. Why was this?

In answer to these statements and questions it may be remarked that the clinical results alone are so gratifying to the patients as well as to the gynecologist that if for no other reason the use of the blue seems to be preferable to the use of other microbicides or to the "let alone," or non-treatment, method advocated by some.

It is true that as yet no scientific proofs have been adduced founded on thorough customary bacteriologic examinations of the secretions by the Gram method before, during, and after treatment. Such data, doubtless, will be forthcoming, whether corroborative of or destructive to the claims of the adherents of the blue method, as soon as a sufficient number of carefully studied cases have been collated to justify such publication. Many cases have been treated during the experimental stage of the use of the remedy in which careful and systematic bacteriologic examinations have not been made, only the final showing after six to twelve applications of the blue being recorded. Such cases cannot be adduced as proof, although these patients do show the clinical amelioration and have been discharged, or have discharged themselves, as cured. It is hoped that gynecological clinics and pathological laboratories over the country will institute a series of experimentations in this line. It will be a simple matter to prove or disprove the gonococcocidal value of the remedy by this method of study. If the various examinations show a diminution in the number of the germs and their ultimate disappearance from the secretions, the claim of a cure will be justified. If they show an amelioration only so long as the remedy is applied, the place of the blue in the category of gonococcocides will be established; for that is just what the various remedies now generally employed do to varying degrees. The relative value of the gonococcocides can then be readily determined. If the "let alone" method be adopted, it stands to reason that no conclusions can be reached either for or against the use of any remedy that may be proposed.

The writer has had practically no experience with the topical application of methylene-blue in male gonorrhea. Therefore, he cannot speak as to its value there. If the blue will destroy the gonococcus at one point, it should be able to do so at another, provided it can be brought into direct contact with the germs. The problem in the male would involve the accessibility to the germs. This would require restricted urethral applications with or without the use of the urethroscope.

As far as can be determined from a review of the literature since the drug was first employed in 1876, its use has been largely limited to internal administration, or, rarely, to intravenous or subdermal injections. During its passage through the body it apparently undergoes some chemical or physical change which renders it practically inert when in the urinary canal. It was doubtless this obscure change in its physical and therapeutic properties which resulted in the abandonment of the remedy when employed in the designated ways. The plea is now advanced for a direct topical use of the blue.

All that the writer invites is a fair, impartial investigation of the blue method with published reports from reliable laboratories and clinical institutions. He would deprecate as unfair a curt dismissal of the matter without adequate inquiry into its merits. His own studies thus far have been most gratifying in their clinical results, and he is ready now to pursue them further in a thoroughly scientific manner.

7 WEST MADISON STREET.

Hearsay Evidence of Physician's Declarations Inadmissible.—In an action for personal injuries evidence of declarations of a physician to the plaintiff's son as to the cause of the injury, was held hearsay and inadmissible in the presence of testimony by the physician inconsistent with such declarations.—Corpus Christi Ry. & L. Co. v. Baxter, Texas Civil Appeals, 217 S. W. 187.

RABELAIS IN LIBRARIES.

By DOUGLASS W. MONTGOMERY, M.D.,
SAN FRANCISCO, CAL.

FOR some time it has been my custom, on visiting a town, to go to the libraries to see what is to be had on Rabelais. I usually find very little and that of the most cursory nature.

The reason for this neglect of the greatest of French authors, and one of the few great literary geniuses of the world, is undoubtedly the grossness of his language, which is probably more accentuated in our literal translations than it is in the original French. Very many of the words employed by us in the common things of life are German-Anglo-Saxon, and come to us from the Saxon serfs and farm laborers, held in menial positions by their Norman French conquerors. With us it amounts to having two languages: one refined and the other vulgar.

I well remember how revolting the word "schmieren" was to an American who had lived long in Germany. She could never get used to the question: "Wollen Sie Ihr Brödel einfach oder geschmiert?" Will you have your roll dry or buttered? This repugnance was all because one word, "smear," is employed in a disagreeable sense. Anyone could give a long list of similar terms having a stronger flavor.

Rabelais employed his frank terminologies probably for three reasons: His genius led him to use the unveiled word just as it was used by the peasantry of Touraine. In addition to this, it must be remembered that Rabelais and Calvin were engaged in raising the French provincial languages into a great national language, just as Luther did a similar service for Germany. Latin was then looked upon as being the only literary language worthy of a scholar, and Rabelais was determined to show that French was capable of serving every purpose in expressing thought. Many of his long lists of words, now so tiresome to readers, had this very end in view, and he took any word that came to hand to force his point home.

Furthermore, in his time, in order to write at all freely on any subject, either in politics, science, or religion, the writer had to hide himself, and this was true of any country whether Protestant or Catholic. The Protestant (Calvin) was as bad in this respect as the orthodox Roman church. Rabelais, therefore, chose to conceal himself under a veil of buffoonery and grossness, and in this he has been so successful that he has practically hidden himself from the common sense reader ever since.

Even in his own day, the great Tourangian was so successful in concealing himself in his own works that he seems to have said almost everything that he wished to say, and yet said his say in such a way that he successfully eluded his very powerful and relentness enemies. Rathery, in commenting on one of the most objectionable chapters in Gargantua, said that this feature of it was what saved both the author and the author's works from being burnt at the stake.

It appears that the clergy of the Sorbonne, stung by some of Rabelais' remarks, entered a complaint against him, and his writings were sent to Francis I for censure. The king was so highly amused by what he read that he sent back word that he could see no evil in the book, although even in the chapter referred to Rabelais took a sly dig at the king himself.

In inquiring at a library for works on Rabelais, one is at first quite sensitive, as the guardian of literature is usually a female, who probably has taken a glance at the great Tourangian's works and has been properly shocked. Therefore, she looks upon everyone reading such a book as an old rip. She is not to be blamed, as it is only of recent years that a different view has been taken, and then only by a group of learned men, mostly French and English.

Usually, as previously remarked, the booty in any library, even the largest, is small, but one gets surprises. In Toronto I ran across W. F. Smith's translation, which has been of the greatest service to me, and I secured a copy immediately on returning home. The translation is admirable, and the notes are most elucidating. With a fair knowledge of French, and with a copy of the original, one has a complete library. As a further aid, there is the recently issued edition of Rabelais by Henri Clouzot with modernized spelling, which wonderfully facilitates reading. By the way, I recently ran across the Henri Clouzot edition in the public library in Victoria, British Columbia. Some lover of Rabelais certainly lives up in that region.

The late Sir William Osler was a great admirer of W. F. Smith, and frequently wrote to me of him, commending him as one of the greatest living Pantagruelists. His work, "Rabelais in His Writings," is excellent reading.

On another occasion I ran across a copy of the edition by Esmangart and Eloi Johanneau in the California State Library in Sacramento. This is a fine work, because of its own intrinsic merits and because it gives so many of Le Duchat's notes.

Recently I went down to Louisville on my way to see the Mammoth Cave of Kentucky. The very name is reminiscent of "La Nouvelle France," that France that extended from Quebec up the St. Lawrence, along the Great Lakes, and down the Mississippi Valley with many a long voyage into remoter regions. Its name is of a piece with that of Detroit and St. Louis, and many another. I found in the library index the name of Sir Walter Besant's work on Rabelais, and on inquiring for it they said it was out. It was probably lost, and with it the Louisville Public Library had lost its entire Rabelais collection. A further acquaintance with Louisville showed it to be a German-American city, and the beautiful library building was camouflage and did not represent the work of their own citizens, but was a gift of Andrew Carnegie.

A few days later I reached Richmond, the capital of the Confederacy, and a most interesting city if for nothing else than its individuality. Baltimore resembles it, but nowhere else do I know of a city just like it. Before the Civil War the Southern gentlemen were particularly strong on the classics, especially the Roman classics. In fact, it amounted to a weakness in them, and for long they troubled Congress with quotations from Horace and other Latin authors, until a member arose one day delivered a fervid oration in an unknown tongue. On being chided, he said it was Cherokee, a per-

fectly good American language much spoken in his district, and that he had as much right to speak it as the other gentlemen had to speak the language of the Roman tribes.

On going to the library in Richmond I felt that those who had a high regard for the older Latin literature would naturally be enthusiastic in regard to the more modern Latin dialect, the French, and that they would be especially enthusiastic in regard to the man who was the pioneer in making that language a classic. I found two editions, the old, excellent but very imperfect, Urquhart edition, and another by Alfred Wallis issued in 1897, and largely a mere reproduction of the Urquhart. This Wallis edition I had never seen before; so that I did not feel wholly unrewarded for my visit.

If, by steady, serious reading, one gets past the dunghill in Rabelais, one enters into one of the most wonderful mansions ever constructed by man. The medical references alone are well worth careful study by any physician. And it is the medical flavor throughout that induces so many physicians to read him, and I believe he has more readers among physicians than in any other class, and it is by no means valueless reading.

The modern surgeon tends to develop into a mechanic with all a mechanic's mental limitations, and the modern physician is so crowded with facts that he has difficulty in seeing the woods because of the trees. The older physicians took broader views; they had to because of the meagerness of scientific knowledge. Rabelais is peculiarly the exponent of the old Galenical medicine with its broad, free lines, and add to this his expansive humor, and an ability for character depiction equal to Shakespeare, and one sees why one obtains from him glimpses of the physical human being such as can be obtained nowhere else. Through Rabelais one may easily return to sanity even after reading attentively and prolongedly, a wearisome, minutely detailed, modern medical paper, and that is some praise. And so it may easily prevent an accident to a patient due to too intense thought and overzeal on the part of the medical man, an accident of not infrequent occurrence. In other words, it achieves what Aristotle used to call a mental catharsis, or cleaning out.

It is interesting and curious that the great Aristotle, that mighty assembler of facts, should have recognized the value of this mental catharsis, which he got by going to the theater.

Medicolegal Notes.

Hospital Records Admissible as Evidence Though Bearing on Liability for Personal Injuries.—Under the Massachusetts statute of 1912, providing that records of cases kept by hospitals shall be admissible, so far as relating to treatment and medical history, but not as evidence on liability, in an action against a street railway for personal injuries, a hospital record relative to the plaintiff was held admissible, despite the statement therein that there was an odor of alcohol on the plaintiff's breath. The difficulty in applying this act arises from the nature of the entries made in hospital records. It frequently must happen that facts stated therein, which deal in the main with the patient's medical history, may also be relevant to the issue of liability, in the event of litigation. For instance, a statement of the location and nature of the patient's injuries, primarily an essential element in the history and treatment of his case, may incidentally tend to confirm or disprove his claim as to how the accident happened. So, the condition of intoxication, in the case of a patient suffering from delirium tremens, would be an important element of his medical history and treatment; at the same time it well might bear upon the issue of liability in an action to recover under the Civil Damage Law. In the Massachusetts Supreme Court's opinion a reasonable and practical construction of the statute requires that a record which relates directly and mainly to the treatment and medical history of the patient should be admitted, even though incidentally the facts recorded may have some bearing on the question of liability. The improper application of the facts recorded can be prevented by means of suitable instructions to the jury.—Leonard v. Boston Elevated Ry. Co., Massachusetts Supreme Judicial Court, 125 N. E. 593.

Compromise and Settlement of Physician's Account.—In an action for the balance of a physician's account for visits the defendant did not dispute that the services had been rendered and that the charges made for them were reasonable, but he did not admit that he owed them. On the contrary, when his attention was called to the account, as he testified, he proposed to settle on a compromise basis, and upon the plaintiff stating that his account was about $400, he stated he would pay $200 if the defendant would accept that in full. Under these circumstances he made out his check for $200, writing on it that it was in full, transmitted it by letter, calling attention to that sum, and the plaintiff cashed the check. It was held that he was bound by his act and could not claim anything beyond the $200. His reception and retention of the $200 in full payment of his account, that not being a liquidated account, that is, agreed upon by the parties, or fixed as to the amount by the operation of law, or an account stated, was conclusive on him.—Booth v. Dongan (Mo.), 217 S. W. 326.

Objection to Physician's Testimony as Privileged Must Be Timely.—In a murder case the state called a physician who testified, in rebuttal, that he called at the county jail to treat the defendant's injuries. He found that he had a cut on his wrist and another on the back of his little finger on the left hand, and gave his opinion that these wounds were not caused by a sharp cutting instrument, but that they were ragged and resembled barbed wire cuts, a number of which the physician had seen. The defendant objected to the admission of this testimony because in violation of Missouri Rev. St. 1909, § 6362, making one's physician incompetent. The physician, however, had testified without objection to the character of the wounds, and had given his opinion that they were not caused by a sharp cutting instrument. When asked for further explanation, objection was made. After the objection was made no material additional information was sworn to by him. It was held that the objection was not timely, and the privilege was therefore waived.—State v. Powell, Missouri Supreme Court, 217 S. W. 35.

Physicians Action Against Husband for Medical Services to Wife.—In a physician's action against a husband for services furnished to the wife there was, or could be found by the jury to be, authority in the wife to contract on the husband's credit for the services under controversy. It was held that the defendant husband's request for an instruction that the burden of proof was on the plaintiff to show that the defendant neglected or refused to provide his wife with the necessaries before the plaintiff could recover was improper, as wholly ignoring the question of the wife's authority and as requiring an instruction that the plaintiff could not recover except on the husband's neglect or refusal to provide necessary medical service.—Vaughan v. Mansfield (Massachusetts Supreme Court) 126 N. E. 376.

Statement That Defendant Physician Protected by Insurance Held Prejudicial.—In an action against a physician for damages for malpractice an uncalled for statement by the plaintiff's counsel in his argument to the jury, implying that the defendant was protected by insurance, was held error necessitating reversal.—Sherwood v. Babcock, Michigan Supreme Court, 175 N. W. 470.

THE ROENTGEN RAY AS A HEMOSTATIC.

THE spleen is a mysterious organ and its functions have been determined only in part. Many of the activities that have been attributed to this organ have not been satisfactorily demonstrated and comparatively few of them are generally accepted as proven. The complete removal of the spleen is followed by such slight disturbance in the chemistry of the body generally that one is forced to the conclusion that, either the functions of the organ are of but little importance or they may readily be assumed by other organs. Pathological activity of the spleen is assumed in a number of the so-called "blood diseases" often chiefly because of the appearance of splenomegaly. Recently the spleen has been credited with a new form of activity, that of the production of a "coagulating ferment." R. Stephan (*Münch. med. Wochenschr.*, lxvii, 309, 1920) claims to have been able to combat successfully the hemorrhage in a case of purpura by exposing the spleen to the *x*-ray. He says that *x*-radiation of the spleen rapidly decreases the coagulation time *in vitro* and that this result is accomplished by stimulation of what he calls the "reticulo-endothelial cell apparatus." The platelet count is not modified. In normal subjects he was able to shorten the coagulation time to one-fourth. The maximum effect appeared in from two to four hours and then gradually subsided. It is generally believed that the roentgen ray depresses lymphoid tissue and this the author does not deny. He maintains that the reticulo-endothelial cell apparatus is wholly distinct from the lymphoid tissue of the spleen and that its reaction is different.

Were Stephan's assumptions correct we would have at hand a valuable aid in the treatment of hemorrhage of many sorts and it is hoped that endeavors will be made to corroborate or to disprove his conclusions. Many hemostatic agents have been proposed but none is uniformly applicable or satisfactory. Normal horse serum may work well but its intravenous use is not free from danger. Cephalin is limited to local application. Serum has been prepared containing prothrombin, antiantithrombin, and thrombokinase and theoretically should answer every requirement. It is said to be adaptable to intravenous use. The testing of these preparations is not simple and Hamilton proposes (*Jour. Lab. and Clin. Med.*, v, 574) that blood be drawn from the carotid artery at stated intervals, the animal being anesthetized and the coagulation time being noted as the point at which the tube of blood can be inverted without fluid being observed. He introduced the serum intravenously and found that the coagulation was shortened to one-fifth or one-sixth in the course of about 1½ hours. No figures are given as to the duration of the effect. The method can be used only for the standardization of those products which can be introduced intravenously and so is limited in its application. The use of either of the above methods, serum or roentgen ray, to combat hemorrhage, is not free from danger and should they both prove to be reliable one would choose carefully between them in each individual case. But it would be cheering to know that two such powerful agents could be obtained in case of need.

EARLY SYMPTOMS OF CANCER OF THE COLON.

To be able to diagnose malignant disease in its early stage affords the only hope of instituting curative measures or of operating in time to give relief for a comparatively long period. But the difficulty is to insure an early diagnosis. Internal malignant disease is as a rule, not discovered until it has reached such a stage that operative measures are almost hopeless. For the fact must be taken into consideration that the real criterion of a successful operation is not a low mortality rate, but rather the length of time before recurrence. It is then a melancholy truth that in the vast majority of cases of internal cancer the diagnosis is made too late to enable one by operation to prolong the patient's life to any extent. Surgeons, however, according to Mr. Seton Pringle of Dublin, writing in the *Practitioner* for July, 1920, are nowadays agreed that the prognosis following operation for early cancer of the colon is more favorable than that for cancer in almost any other part of the body. The growth remains local in the wall of the gut for a long period; it is rarely disseminated by the blood stream, and the arrangement of the lymphatic vessels and glands is such as lends itself to a true radical or en bloc operation, an operation in which the primary growth, the lymphatic glands and the lymphatic vessels connecting the two are removed all in one piece.

The results of Pringle's investigations with regard to patients upon whom he had carried out such an operation some years ago, show that 40 per cent. had recurrence within periods of less than two years, while only 30 per cent. survived more than five years. Closer investigation shows that of all the cases operated upon only 37 per cent. were uncomplicated, or what might be termed

early cases. It is Pringle's belief that most cases of cancer of the colon can be diagnozed long before the classical signs and symptoms of the disease develop, and even if a definite diagnosis cannot be made, the presence of a cancerous growth can be suspected so strongly as to justify a timely exploratory operation. He is of the opinion that the logical manner in which to approach the diagnosis of any disease is to study its pathology and symptoms and to correlate the two.

Following such a method we find that the essential pathology of cancer of the colon might be epitomized into four stages—tumor, ulceration, stenosis, and dissemination. Pringle holds that when the tumor is in the pelvic colon and cannot be palpated, the evidence of ulceration manifested by blood in the stools is strongly enough indicative of malignancy to justify an exploratory operation. As for the diagnosis of stenosis, this condition is evidenced by several signs. For example, a patient whose bowels have previously been regular finds that instead of one good motion a day he passes two or three small ones, and similarly a patient who has formerly had recourse to regular aperients finds that the same dose, instead of giving one or two fairly large motions, now produces from four to six smaller ones. Also associated with the disturbance of function there is frequently a feeling of dissatisfaction as if the bowel had not been properly emptied. The syndrome, then, comprised of the passage of blood, mucus, and pus with an increase in the number of daily evacuations, together with this feeling of dissatisfaction, is characteristic of early stricture of the bowel associated with ulceration, and the only common cause of this condition is cancer.

Taking everything into consideration and recognizing the great risks that are run by not diagnosing cancer of the colon in time for operation to be effective, Pringle urges that cancer in this locality should be treated on the same lines as acute appendicitis. Not so many years ago cases of this disease were carefully watched for the outset of so-called "indications for operation," whereas, nowadays, the only indication the surgeon requires is evidence of acute inflammation in the right iliac fossa. Similarly, he believes the persistence, without discoverable cause, of the symptoms enumerated above is sufficiently suspicious of cancer of the colon to justify an exploratory operation. Moreover, very rarely in Pringle's experience, has such an exploration resulted in a negative finding.

THE PATHOGENESIS OF PARALYSIS OF THE LEFT RECURRENT NERVE IN MITRAL STENOSIS.

THE pathogenesis of paralysis of the left recurrent nerve in mitral stenosis has given rise to numerous hypotheses, some of which have been confirmed by autopsy or by radioscopy, others based only on the interpretation of the symptoms offered by the patient. The first theory is due to Ortner, who was led to regard paralysis of the recurrent as caused by compression of the left nerve against the bend of the aorta by the considerably dilated left auricle. Autopsy had revealed this compression with the nerve thinned and degenerated at the point of compression. The second theory is due to Kraus, who found at autopsy a considerable dilatation of the left auricle, but without contact between it and the aorta. Such contact appeared an impossibility to this observer since the left branch of the pulmonary artery was placed between these two organs. On the other hand, Kraus noted that the right ventricle, which was greatly increased in size, lay on the diaphragm, having produced a kind of torsion of the heart, with the consequence that the pulmonary artery was dragged upon, and then the aorta by the intermediary of the arterial canal, and finally elongation of the recurrent ensued from the lowering of the aorta. This rather complicated theory was accepted by clinicians, or at least it was held to explain certain paralyses of the recurrent nerve in mitral stenosis at the time of compensation when hypertrophy of the right ventricle takes place. Ortner's theory was even applied in explanation of late paralyses arising in mitral asystolia. Quadrone went to the trouble of extending Kraus's theory, inasmuch as he attempted to explain bilateral paralysis of the recurrents in seven cases of mitral stenosis by displacement as far up as the subclavian artery. Soon, however, Dmitrenko, Fetterholf, and Norris took up the subject and came to the conclusion that neither Ortner nor Kraus was correct in this pathogenic interpretation. They held that the recurrent cannot be directly compressed by the auricle and that there is always an interposition of the pulmonary artery. Then Gellies reported a case of paralysis of the recurrent due to compression of the inferior laryngeal against the aorta by the left branch of the dilated pulmonary artery. Enlightened by this fact, clinicians came to the natural conclusion that the pulmonary artery must be regarded as the mediate but necessary agent for compression of the recurrent. Alexander admitted this theory and from the study of a radioscopic picture he concluded that there was, in some cases, a direct compression by the pulmonary artery without the interference of the auricle. Such is the third explanation of paralysis of the left recurrent in mitral stenosis.

What is to be thought of these three theories? In the first place, that of Kraus should be rejected, because the aortic arch is too solidly fixed to be moved by traction of the frail remains of the ductus arteriosus, and it does not necessarily follow that the base of the heart becomes lowered when the right ventricle dilates. Dilatation of the right heart is frequent in many cardiac processes and paralysis of the recurrent nerve is very rare, usually only to be found in mitral stenosis. Given the precision of the autopsy findings, it is difficult to doubt Ortner's theory, but in spite of all, it is easy to admit that the pulmonary artery becomes inter-

posed between the aorta and auricle, especially when it is recalled that the pulmonary artery is dilated in mitral stenosis. But Lian and Marcolles very properly point out that great dilatation of the left auricle is frequent in mitral stenosis, while paralysis of the recurrent is rare, and they believe that if auricular ectasis can produce compression, other factors must exist at the same time, such as an old thrombosis of the left auricle or a certain degree of chronic mediastinitis. The latter lesion seems to them essential in order to explain the inequality of the radial pulses which, according to Popoff, has been observed in a number of cases of mitral stenosis. The recurrent nerve, comprised in the products of a chronic mediastinitis, is more sensitive to the mechanical influence of a dilated left ventricle and pulmonary artery, so that in this way may be explained the recrudescence of recurrent nerve disturbances when an attack of asystolia occurs. The mediastinal inflammatory reaction provoked by a mechanical irritation is all the more readily produced, because in mitral stenosis the subjects are often tuberculous or even syphilitic at the same time. Lian and Marcolles accept Alexander's theory, but they rightly ascribe a large part in the process to mediastinitis. It is also probable that the purely mechanical theories are insufficient and that paralysis of the left recurrent is rather more the consequence of a certain degree of mediastinal inflammation surrounding a dilated left auricle. The existence of this complication of mitral stenosis should attract attention on account of the diagnostic mistakes that might arise, especially with aneurysm of the aorta.

THE EARLIEST MEDICAL MEN IN ANCIENT ROME AND ITALY.

RAULIN contributes an article on this subject in the *Gazette hêbdomadaire des sciences médicales de Bordeaux* for July 4, 1920, xli, 27. The earliest known race of men to settle in the peninsula were the Liguri, now believed to have come from North Africa, who incidentally occupied the Roman campagna, but left no monuments. Next we hear of the Etruscans who once dominated most of the peninsula and who are believed to have migrated from Asia Minor. They developed a marvelous civilization which comprised some remarkable prosthetic dentistry. The third race to reach the peninsula were the Proto-Latins—Umbrians, Sabines, etc. The first medical man in Italy whose name has come down to us was Aschagaton, a Greek, about 219 B. C. The nature of his welcome appears to indicate that he was the first practitioner having any pretensions to scientific knowledge. But he was followed by the slave-physicians in large numbers, individual members of the caste acting as medical advisers to the households of the well-to-do. These were principally Greeks and practised numerous specialties. When they had received their liberty they practised under the name of "Free Physicians."

From another viewpoint the old Romans, who anticipated so many of our economic customs, had city or public practitioners who gave first aid and realized the modern ambulance service. They were to be found at fixed posts. These or other bureaucrats also acted as district physicians to the poor and there were 14 such, one for each district. This custom prevailed in the days of the Republic, and later under the Empire.

The success of Aschagaton the Greek was followed by an inrush of medical adventurers who exploited their clients to such effect that Sylla was obliged to pass restrictive laws. Next to Aschagaton we hear of Asclepiades of Bithynia, who was a well known medical figure in Rome, dying in 96 B. C. He practised the art of Hippocrates well. Musa had the honor to be the personal physician of Octavius. Equally well known was Lucius Horatillavus, a native Italian physician, who earned a large fortune. From this time on, the medical men, beginning with Celsus, are well known to medical readers.

LATE CHLOROFORM DEATH IN HEPATIC CASES.

BRUNNER of Zurich writes briefly on this subject in the *Schweizerische medizinische Wochenschrift* for June 17, 1920, i, 25. In animal experimentation chloroform is not given if hepatic lesions are present. The author has had two experiences which convince him that the same risk obtains in man. The first occurred in 1905 when he operated on a healthy looking woman aged 52 for a postoperative abdominal hernia, the first intervention having been for adnexal disease. Sixty grams of chloroform were given in this second intervention. On the third postoperative day, after she had been doing well, icterus appeared with restlessness and benumbing of the mind and disturbed respiration. Death took place the same evening and autopsy showed pronounced hepatic cirrhosis without other finds. In 1915 he operated on a 70-year-old man with ileus and mesenteric thrombosis and the outcome was the same. In the absence of other factors it is fair to accuse the chloroform as the cause of death, this veiw being corroborated by the experience of other operators.

Speaking generally of late chloroform death the finds include a condition of the liver closely resembling acute yellow atrophy. These deaths usually follow operations for acute abdomen due to various causes in which the portal circulation is involved. In order to produce at will in the dog late choloroform death it is only necessary to establish beforehand an Eck fistula. In discussion Henshen spoke of a somewhat analogous experience in which ether was used as an anesthetic in gallstone surgery. In such cases the kidneys, liver, etc., may be compromised at the time of intervention. In all operations on the portal distribution he first tests the functions of both kidneys and liver irrespective of the anesthetic which is to be used.

Psychic Inhibition of Menstruation.

Stoltz, the old authority of Strasbourg in the middle of the last century, regarded the menstruating woman as almost a sick woman, and it has remained for some of his successors in the chair of obstetrics to demonstrate that many menstruating women present not the slightest evidence of illness aside from a loss of blood. With such a tendency to dissociation almost anything affirmed of menstruation may be disputed. Psychic suppression of the menses exists but cannot be very common. Deluis once published notes of 60 cases. Christides of Geneva has recently added a case of this sort to the recorded material (*Revue française de gynécologie*, February, 1920, xv, 2). The young woman was aged 28 and presented a history of renal crises with anuria, passage of calculi, and hematuria. After several of these crises, for which condition operation was refused, her menses ceased. Placed under observation she went through one of her attacks of renal colic, accompanied this time by symptoms of acute abdomen. She was found to have appendicitis and the offending appendix was at once removed. On the occasion the surgeon examined the urinary passages and four weeks after the appendectomy performed an operation on the kidney, the details of which are not given, but it was evidently only a capsulectomy for the relief of intrarenal tension. A new renal crisis followed. Suspecting a psychic factor the subject was psychoanalyzed, and a study of the supposed calculi by Askanazy revealed that these were only clots. It was learned that a certain degree of purulent cystitis was present and simulation was at once suspected. During the period of internment the menses were almost but not quite suppressed, although a marked menstrual molimen was present. Psychoanalysis failed to reveal anything, but the woman improved and her menses returned, with cessation of the renal crises. The case was not fully clarified, but apparently there had been a suppression of menstruation in a profoundly hysterical subject, with a molimen which was severe enough to simulate a renal crisis. The appendicitis must have aggravated the state of affairs. Either when fully conscious or during a hypnoid state the woman introduced into the bladder some foreign objects which simulated calculi or clots and set up a gaseous cystitis, thus adding notably to the picture of renal colic.

Relations of Neurasthenia to the Psychoses.

In an article on this subject in the *Journal de médecine et de chirurgie pratiques* of April 10, xci, 7, Mercier seeks to delimit the former affection, which he says is manifestly of two different types. In one there is no predisposition and the exhaustion of the nervous system from overwork is manifested by "helmet" headache, backache, insomnia, vertigo, neuromuscular asthenia, moral depression, and gastrointestinal troubles, to go no further. In the other type the motivation is endogenous, predisposition is everything. It is often seen in the adolescent who, after having always proved equal to his studies and play, becomes fatigued after insignificant exertions. The somatic manifestations are much as in the acquired form, although seldom pronounced. Instead we see doubts, scruples, phobias and obsessions, impulsions, etc. According to Magnan and others, these subjects are psychopathic degenerates. Recently Delmas has proposed to call endogenous neurasthenia "obsessional psychosis," but the author is not with him in this interpretation. The mental state is a direct consequence of exhaustion of the nervous system. With marked somatic symptoms these psychic peculiarities may be masked or blunted. In acquired neurasthenia, too, the emotional or affective state is exaggerated, the subject is depressed and pessimistic, small happenings are magnified, there is doubt in place of certainty, the external world and one's self seem strange and unreal, there is the feeling of *déjà vue*, of dissociation of personality, etc. A distinction between ordinary neurasthenia and the psychasthenia of Janet is not recognized by the author. The many phobias and obsessions are not to be regarded as something outside of neurasthenia, but as belonging to it. The doctrine of Freud which make of these fears and obsessions an anxiety neurosis of sexual origin is not shared by most neurologists. In regard to melancholia some melancholics are neurasthenics pure and simple, while between this type and melancholic psychosis every transition is seen. So long as delirium is not present, the neurasthenic component is probably dominant. The diagnosis between melancholia and neurasthenia is all but impossible in many cases. Hypochondriasis is best regarded as a mere symptom common to various mental affections.

The Facial Traumatisms of Boxing.

Dr. Boigey, a gymnasium physician in the French military service, discusses this subject in *La Presse Médicale* for April 21, 1920, xxviii, 24. The injuries are either common in type or characteristic of the sport. Under contusions are comprised simple ecchymoses and hemorrhagic infiltrations, accompanied at times by lacerations and disinsertions of the nasal cartilages. The cartilaginous part of the nasal skeleton becomes somewhat flattened from repeated blows. The chin is the only part of the face which escapes the consequences of severe blows and never shows the effects of punishment. It behaves as a shock absorber. Extravasation of blood into or around the jaw muscles rarely causes a sort of lockjaw and blood may escape into the mouth through Steno's duct. The fatty pad of Bichat behind the ascending ramus of the jaw may inflame and the condition may last for more than a week. In the well-trained man this pad is, of course, absorbed for the time being. But it is the ear which shows the most characteristic results of contusion. The helix and adjoining groove may be obliterated; or otherwise stated, the helix and antihelix may become consolidated. The concha becomes very shallow from thickening of its wall. A hematoma often forms in the substance of the external ear which is the cause or result of separation of the skin from the cartilage. The membrana tympani is sometimes ruptured and the ossicles of the middle ear are compromised. Secondary infection of the tympanum with otosclerosis and deafness may result. Functional derangements in the labyrinth

are described. Compared with the ear the eye shows no serious damage. Detachment of the retina—which accident once befell Roosevelt as a result of a blow received while boxing—is not mentioned. Dislocation at the temporomaxillary articulation is not infrequent. Fractures of the nose and lower jaw are extremely common. When the nasal bones are driven inward blood may escape from the puncta lacrymalia. Vicious union of nasal fractures leads to marked deformity with functional disability, which requires surgical relief before the boxer can resume his calling.

Recent Progress in Gynecology and Obstetrics.

In the Gynecological-Obstetrical number of *La Médecine* for April, 1920, i, 7, Devraigne attempts to show the progress and status of these specialties during the four years of warfare. Serodiagnosis of pregnancy of which so much was expected has apparently not advanced, despite the abundance of theoretic possibilities which have come to light. We have numerous methods, including variations, but in practice we are not aided. The operative and radiation treatments of cancer of the cervix are in a satisfactory condition, but the problem of educating the public and of early intervention is not being solved. The war should stimulate the science of obstetrics, for the need of a greatly increased birthrate bears on such subjects as painless labor and proper hygiene of the puerperium. If we expect the modern woman to bear double the number of children we must make labor as simple as possible. The general idea of painless labor is, of course, excellent, but the problem must be individualized not only for the patient herself but the particular stage, etc., of labor. There have been no important direct advances against sterility, but the attempts to cure fibroids and metrorrhagia by radiation may be regarded as a step in that direction. The subject of surgical intervention during gestation takes on new importance as does anything which threatens interruption of pregnancy, whether it be an operable disease or the operation itself. Hysterectomy in adnexial suppurations and other sterilizing procedures may have a significance at present not ordinarily possessed.

Autoserotherapy of Gonorrheal Epididymitis.

Marinesco of Bucharest makes a brief contribution to this subject in *La Presse Médicale* for May 19, 1920, xxviii, 32. The effect of epididymitis in checking the parent urethritis has led the author to assume the formation of an antibody. The method of autoserotherapy was initiated originally by Gilbert, while Maillet and Ramond made a special application of the principle in gonorrheal arthritis. The author has therefore applied it to the cure of epididymitis and vaginalitis of gonorrheal origin. The first patient treated was a student with a urethritis of two weeks standing. While under treatment he was compelled to make military marches, with the result that epididymitis developed with fever and appearance of fluid in the vaginalis. The latter was punctured and the punctate, which was 2 c.c. in amount and slightly cloudy, was injected into the subcutaneous region of the thigh. The following day the patient was much improved in every way and at the end of eight days the treatment of the urethritis was resumed and the patient was soon well. The second case was in a man of 32 with right epididymitis and funiculitis complicating a gonorrhea of four months standing. This complication was acute, with marked fever and pain. Five c.c. of serum was recovered from the vaginal exudate and injected under the skin of the thigh. Within 24 hours there was a remarkable change for the better. The injection was repeated twice and there resulted a complete cure without resort to any other treatment. The author has a high opinion of this plan and if he encountered a case without the complication of vaginalitis would proceed by injecting 10 c.c. of the venous blood, a method in use by him in ordinary infections without effusion.

News of the Week.

Name Canal Zone Road for Major General Gorgas.—Among other memorial tributes paid to the late General William C. Gorgas, who died in London on July 4, the following circular, according to the *Army and Navy Journal*, was issued by the Governor July 8: "The road leading from Ancon post office through the grounds of Ancon Hospital to the top of the hill at the women's bachelor quarters, and known as 'Hospital Road,' is designated 'Gorgas Road' in honor of the late Major Gen. William C. Gorgas, U. S. A., former member of the Isthmian Canal Commission, and in commemoration of the many distinguished services rendered by him."

Study Bubonic Plague.—Dr. Hugh S. Cumming, Surgeon General of the United States Public Health Service, left for Galveston August 1 to attend the national conferences of State and city health officers, held August 3 and 4, for the purpose of considering measures for the eradication of bubonic plague.

First Medical Journal in Palestine.—"*Harefooah*" (*Medicine*), published by the Jewish Medical Association of Palestine, has just made its appearance, according to a statement issued by the Zionist Organization of America. The journal will be issued quarterly. Its first number is dedicated to the memory of the Jewish physicians and nurses who "lay down their lives in the years of upheaval in the Holy Land." The objects of the medical association, as outlined in the quarterly, are to strengthen and coordinate the medical forces of the country and to collaborate with doctors outside Palestine; to give the medical work a national as well as a humane value; to prepare a native soil for Jewish scientists; and to help in the creation of the Hebrew University.

Suicides of Women and Children Increase.—It is shown by the semi-annual report of the Save-a-Life League, an organization devoted to the prevention of suicide through prompt and quiet relief of acute distress, that there were 961 suicides of women in the United States during the first six months of the present year out of a total of 2,771 suicides. This is said to be a marked increase in the number of suicides among women, and it is attributed to the entrance of women into business and politics, with consequent complexity of their

lives. During the same period 88 boys and 137 girls committed suicide in this country, an increase of fifty over last year's report for the same length of time. The average age of the boys is sixteen and of the girls fifteen years.

Opposition to Vaccination Drive.—The New York City Department of Health, in its recently inaugurated vaccination drive against smallpox has found strong opposition in the more crowded sections of the city where epidemics are most apt to occur. The department physicians and inspectors, according to Dr. Royal S. Copeland, Commissioner of Health, have found whole blocks where their efforts to vaccinate families met with obstruction. The commissioner attributes this unwillingness to be vaccinated to ignorance regarding the value of vaccination. There were nine cases of smallpox in the city on August 4.

Typhus Develops on Ship.—When the French liner *Savoie* arrived at New York from Havre August 2 she was held at Quarantine for a few hours on account of a case of typhus fever that developed among the steerage passengers. The victim, a Rumanian youth of 24 years, was sent to Swinburne Island and 517 other steerage passengers were sent to Hoffman's Island for observation for twelve days. This was justified, as two more cases developed the next day. The two patients, both boys, were sent to Swinburne Island.

Free Radium Treatment for Cancer.—The gram of radium recently received by the State of New York for the State Institution for the Study of Malignant Diseases at Buffalo will be available for use in the treatment of cancer after October 15. According to Dr. Harvey R. Gaylord, director of the institution, treatment will be free to any citizen of the United States, but preference will be given to residents of New York State.

Smallpox on Ward Line Steamship.—A case of smallpox discovered among the steerage passengers on the Ward liner *Morro Castle*, which arrived at New York from Havana August 4, caused the vaccination of all cabin and steerage passengers. The smallpox patient was sent to Swinburne Island, while the rest of the steerage passengers were sent to Hoffman's Island for observation.

Psychopathic Ward for Reformatory.—Following a recent race riot and other disturbances at the State Reformatory for Women at Bedford, N. Y., a psychopathic ward has been established with the assistance of physicians and nurses from Bellevue Hospital. Hydrotherapeutic measures, hot and cold, have been employed for calming the nerves of the disturbers, presumably with salutary results.

New Law Needed?—It is recorded in the daily press that the Chicago Corporation Counsel's office has invoked an English law five hundred years old in a legal battle to establish the city's right to isolate a woman declared by the department of health to be a typhoid carrier. This ancient act, the writ de leproso amovendo, was incorporated in the English common law, and pertained to the detention of lepers. The outcome of the court's decision will be interesting, in any event.

Dr. Charles G. Child, Jr., of New York City, has been appointed Consulting Gynecologist to St. Bartholomew's Hospital, New York, and to Nassau Hospital, Mineola.

Visiting Nurses Busy.—The Visiting Nurse Service, which operates eighteen nursing centers in Manhattan, The Bronx, and Richmond, reports that the 162 nurses and 72 students of the East Seventy-ninth Street center made 30,956 calls on 5,493 patients during the month of July.

Epidemic of Homicides.—According to the Homicide Bureau of New York City there has been an epidemic of homicides in this city, fifty-two having been committed during the first six months of this year in Manhattan alone.

Life-Saving Day.—The Coroner of the city of Chicago is planning a campaign of education for motorists and pedestrians in an effort to lessen the number of automobile accidents and deaths. On a day known as "Life-Saving Day" pamphlets will be distributed with "Don'ts" for motorists and pedestrians, and statistics showing the large number of accidents.

Another Anthrax Case at Bellevue.—The nineteenth case of anthrax at Bellevue Hospital, New York City, during the last five years is being treated with the serum, with fair chances of recovery.

Laboratory Training for Nurses.—Owing to the apparently increasing demand for graduate nurses who are also proficient in laboratory technique, a course of instruction has been arranged by the Massachusetts Homœopathic Hospital. The course consists of continuous work for one year in the laboratories of Boston University and of the adjoining hospital. It includes didactic and practical instruction in bacteriology, hematology, uranalysis, and serology together with the actual performance of large numbers of the various tests and examinations that come within the scope of a general pathological laboratory. Arrangements have been made to include instruction in and practical induction of anesthesia for a period of three months. No fee for the course will be made, each student receiving board, room, and laundry during the period of her stay. In certain instances an additional period of three months can be arranged for instruction in *x*-ray technique. All applications should be addressed to Dr. H. M. Pollock, superintendent, Massachusetts Homœopathic Hospital, Boston, Mass.

Physician Needed.—The town of Millersville, Anne Arundel County, Maryland, through one of its citizens, has appealed to the State board of health to assist it in finding a physician who will come into the community and establish an office. Barring the medical officers at Camp Meade, there is not a physician within a radius of nine miles of the town.

Medical Society Meetings.—The Southern Medical Association will meet at Louisville, Ky., November 15-18, 1920, one week later than the date originally set.

The Medical Society of the Missouri Valley will hold its thirty-third annual meeting at Omaha, Neb., September 6-7, under the presidency of Dr. Charles Ryan of Des Moines, Iowa.

Medical Society Meetings.—The fifteenth annual session of the Medical Association of the Southwest will be held at Wichita, Kan., September 27, 28, and 29. The first day will be given up to a reunion of medical officers who were in active service during the World War.

Obituary Notes.—Dr. CHARLES H. ALTHOUS, a retired surgeon, died in Bellevue, New York City, August 1, at the age of eighty-five.

Dr. JAMES J. CONCANNON of New York City, died August 1, after a lingering illness, at the age of sixty-four. He was graduated from the College of Physicians and Surgeons in 1890, and specialized in otolaryngology.

Dr. HAROLD LEE MEIERHOF died August 12 at Mount Sinai Hospital, New York City, where he was serving as interne. He was twenty-seven years of age.

Correspondence.

OUR LONDON LETTER.

(From Our Own Correspondent.)

LONDON, July 16, 1920.

Memorial Service to General Gorgas at St. Paul's Cathedral.—There is no need here to refer at length to the great services that the late General Gorgas rendered to public health and thus to the entire human race by the sanitary work that he conceived and in every instance successfully carried out. As the writer of his obituary which appeared in the *Lancet*, July 10, last, said, "He was the best-known and most uniformly successful medical administrator, not of his age alone, but of any age, and his work is comparable only with that recorded of Moses. No sooner were discoveries made tracing an endemic disease to a source removable by rigid hygienic measures than the services of this master-administrator were requisitioned to the farthest quarter of the globe to carry out such measures. And as if by magic, black magic as it appeared to the slovenly, careless inhabitant while magic to the admiring world outside, the areas were cleansed and freed." However, as said before, all this is known well to the American medical man and it only remains to describe the manner in which the British nation showed its whole-souled appreciation and recognition that when General Gorgas died in London the loss was an international one and especially touched the heart of a people who with the Americans speak the same language and in the main possess the same ideals. Thus on Friday, July 9, the British nation paid the highest tribute to the late Major-General William Crawford Gorgas it can pay to the honored dead. With full military honors the body was conveyed to St. Paul's Cathedral, where the first part of the funeral service was held previously to the transportation of the remains to America. The ceremony was magnificent and solemn for which no precedent exists. It is true that a service of supplication was held in the Cathedral on the burial day in September, 1901, of President McKinley, and a commemoration service was held in the same great church when John Hay, Secretary of State of the United States, died in July, 1905. But this was the first time that the mortal remains of a famous American were actually carried into St. Paul's for funereal honor. The King was represented by Lieut.-General Sir H. T. Goodwin, Director-General of the British Army Medical Service; Queen Alexandra by Colonel Sir Henry Streatfield; the Duke of Connaught, who is Colonel-in-Chief of the Royal Army Medical Corps, by Colonel Sir Edward Worthington, and His Majesty's Government by Dr. Addison, M. P., Minister of Health. Borne on a carriage fixed over one of the guns of N Battery, Royal Horse Artillery, the coffin, covered with the Stars and Stripes, and with one beautiful wreath upon its lid, that of the late General's widow, was escorted from Queen Alexandra's Military Hospital, where the death took place, by six pall-bearers, all officers of high military rank. Headed by the band of the Coldstream Guards, the procession consisted of the Staff of the Second Guards Brigade, three squadrons of the Second Life Guards, Third Battalion Coldstream Guards, and the First Battalion Irish Guards. At the steps of the Cathedral the coffin was met by the following, who acted as additional pall-bearers: Military Attaché, United States Embassy; Naval Attaché, United States Embassy; Sir George Makins, President of the Royal College of Surgeons; Sir Norman Moore, First President of the Royal College of Physicians; Sir Anthony Bowlby, Vice-President of the Royal College of Surgeons; Surgeon Rear-Admiral Sir Robert Hill, Director-General Medical Department of the Navy; Brigadier-General John Finney, U. S. Army Medical Service; Surgeon-General Sir Richard H. Charles, Dr. Charles Mayo of Rochester, Minn.; Sir Humphrey D. Rolleston, President of the Royal Society of Medicine; Prof. W. T. R. Simpson, C.B., Vice-President of the Society of Tropical Medicine and Hygiene. Receiving the coffin at the west end of the nave, the Cathedral clergy and choir, headed by Dean Inge, walked before it toward the chancel singing the opening sentences of the Burial Service. The service ended by the band of the Life Guards and the full choir of the Cathedral rendering the "Battle Hymn of the Republic" and the band playing Chopin's Marche Funèbre.

The Death Rate of Influenza in England and Wales.—The Registrar-General of England and Wales has issued recently an elaborate analysis of the mortality in those countries from the influenza epidemic of 1918-19. In this analysis it is estimated that the total number of deaths directly or indirectly attributable to the outbreak was 200,000 or thereabouts. A mortality so high from influenza is unprecedented and exceeds even that from the cholera epidemic of 1849. The report of the Registrar-General states: "The deaths allotted to influenza during 1918 numbered 112,329, 53,883 of males and 53,446 of females. The 53,883 males included 7,591 non-civilians. Deducting these we are left with 104,738 deaths of civilians, corresponding to a mortality of 3,129 per million civilian population. No such mortality as this has ever before been recorded in England and Wales since registration commenced, except in the case of the cholera epidemic of 1849, when the mortality from the cause rose to 3,033 per million population. None of the previous outbreaks of influenza can compare in mortality with that of 1918-19. During the forty-six weeks, June 23-May 10, the total deaths allocated to the disease were 151,446, including 140,989 of civilians, the corresponding civilian death-rate for these forty-six weeks being at the annual rate of 4,774 per

million population." The report goes on to say that it is well known that during influenza epidemics the mortality attributed to the disease does not represent the whole of that caused by it. The entries under other headings, especially those of respiratory disease, are always found to increase during an epidemic, and though this did not occur in 1918 to the extent as in other recent outbreaks, it is still necessary to make allowance for these increases of mortality, allocated to other causes but really attributable to influenza, in endeavoring to measure the loss caused by the epidemic. "Including in the figures the deaths to which pneumonia, bronchitis, heart disease and phthisis contributed, the totals for the third quarter of 1918 were: males, 8,088; females, 7,741; while for the fourth quarter, when the epidemic was at its height, they were: males, 51,359; females, 64,000. The total deaths in 1918 due to the outbreak are estimated at approximately 140,000. The estimate of civilian deaths for the whole epidemic, June 23, 1918, to May 10, 1919, is as follows:

	Civilian Males	Females	Total
June 23 to 30.....	250	250	500
July 1-Sept. 30.....	8,000	9,000	17,000
Oct. 1-Dec. 30.....	51,000	64,000	115,000
Jan. 1-March 31....	22,500	24,500	47,000
April 1-May 10.....	2,500	2,250	4,500
Total	84,000	100,000	184,000

"In addition to the above there were 7,591 deaths of non-civilian males in England and Wales allocated to influenza in 1918 and 2,899 in 1919 during the epidemic period, or 10,490 in all. The number has to be increased to an uncertain extent, say to 14,000, to allow for deaths really due to influenza but allocated to other causes. The non-civilian mortality of the preceding years was so small that it may be left out of account. The addition to the civilian deaths brings the total to 198,000, and in view of the uncertainties of the estimation the round figure of 200,000 deaths attributable to the epidemic, in addition to about 7,000 which the average rate of recent mortality would have accounted for, may be accepted as adequately summing up its results."

Testimonial to Sir John Macalister.—On the afternoon of July 8, at the rooms of the Royal Society of Medicine, before a large gathering of his medical friends, a check for a substantial sum was handed to Sir John Macalister, the secretary to the Royal Society of Medicine, as a token of appreciation for many years' service to the profession and the public. Sir Humphrey Rolleston, president of the society, in presenting the check said that their guest was a very human man and the natural result was that testimony to his great work had come from all parts of the world. Another speaker, Sir Arbuthnot Lane, said that Sir John was "a man who does and never talks." In returning thanks, Sir John said it was the first time in his life he had received a "tip." He had not served the Society of Medicine for money. He thanked many able members of the medical profession for their kindness and assistance, but above all he must pay a tribute to his "alter ego," Miss Willis, his secretary, who had always supported him in his plans.

Dinner to Dr. Charles Mayo in London.—On the evening of July 6 last, a dinner was given to Dr. Charles H. Mayo of Rochester, Minn. As a matter of fact the dinner was given with a double object, to pay a compliment to Dr. Charles Mayo, who is well known and highly appreciated by the profession in this country, and to endeavor to fix public notice upon the scheme to found an American hospital in London, concerning which a good deal has been written in previous letters. The hosts at the dinner were Lord Reading, the president and the governor of the proposed or, rather, projected American hospital. The two toasts given were the health of Dr. Mayo, by Lord Reading, and "Prosperity to the American Hospital in London," given by Mr. Balfour. In replying to his health, Dr. Mayo sketched what true intellectual union between England and America might bring about, and while deprecating the idea that he was a harbinger of disaster, forecasted what war in the future would mean, and recommended that medical preparations to cope with wholesale scientific destruction ought now to be made. Mr. Balfour, in wishing good luck to the American hospital in London, laid particular stress upon the need for and value of mutual understanding between America and this country on questions of medical science. He affirmed as his strong opinion that nothing could more surely assist in accelerating the already wonderful progress of medicine and surgery than a practical exchange of their experiences between professors, teachers, practitioners, and even students of the two countries, such as only could be got by personal conference and could never be supplied by any written medium. This toast was responded to by the American Ambassador and Sir Arbuthnot Lane. Sir Arbuthnot Lane gave a rapid survey of the evolution and development of the idea of founding an American hospital in London. He credited Mr. Philip Franklin with originating the scheme and told how it had taken root and flourished on both sides of the Atlantic, until it was now approaching fruition. He thought it was destined to achieve much in the future, both in the promotion of a good understanding between the two English-speaking countries and in the opportunities and facilities for research afforded. All the speakers referred in sympathetic words to the death of Surgeon-General Gorgas and deplored that so great a career should have been so sadly cut short, whose life work formed a perfect example of what internationalism in medicine could achieve.

OUR LETTER FROM GENEVA.

(From Our Regular Correspondent.)

GENEVA, July 1, 1920.

Action of Paraoxyphenylethylamine.—Azarapetain, working in the Laboratory of Experimental Therapeutics of the University of Geneva, has recently reported on the pharmacodynamic action of paraoxyphenylethylamine, a medicament which possesses great therapeutic interest. This substance is active, but of relatively little toxicity. Rabbits

tolerate from twenty to twenty-two centigrammes per kilogramme of animal, given intravenously, even when the solution injected is very concentrated, say at 10 per cent. As a rapidly fatal dose, 30 centigrammes per kilogramme in a 10 per cent. solution intravenously represents the average in the rabbit and death is extremely rapid. The animal dies like one who has been given a large dose of potassium, but while in the latter the heart stops in diastole, paraoxyphenylethylamine first produces a sort of tetanization of both ventricles before the heart ceases to beat.

In some instances, in spite of an injection of a very large dose, death may be delayed. The animal appears to recover from the injection, but dies later within six to eight hours. At autopsy the bronchi and trachea are found filled with a frothy liquid—pulmonary edema. Other than the cases where autopsy revealed pulmonary edema, no other macroscopic lesion was found in any other organ which could explain the cause of death. The extreme paleness of the brain is striking in acute poisoning.

Large doses of the drug produce convulsions the mechanism of which is far from being clear. At times the eclamptiform paroxysm depends upon an influence directly exercised by the poison on the nervous centers; at others it is the result of severe bulbar anemia due to arrest of the heart's action. In fact, the convulsive state may appear while the heart—although slackened—still beats energetically and the blood-pressure is raised; therefore, only a neurotic action can here be invoked. On the contrary, in other experiments the heart suddenly becomes weak and stops, while convulsions occur which cease when massage of the organ is practised, only to return when massage is stopped.

In these circumstances it is difficult not to admit the convulsions are the consequence of bulboprotuberential anemia; if the animal is left free an intravenous injection of a large dose of the drug will cause a violent forward jump after the lapse of a few minutes, a fall on the side in convulsions, and an almost immediate death. Large doses of the drug may also determine a temporary paresis, particularly of the hind limbs.

Paraoxyphenylethylamine has a distinct cardiovascular action in doses of five to ten centigrammes per kilogramme; it is a tonicardiac medicament, raises the blood-pressure, slows the heart, and increases the amplitude of the pulse. The changes in the pulse are principally due to a direct action of the drug on the heart; also partially to a central action by the intermediary of the vagus. The cardiovascular action becomes manifest rapidly, often at the very onset of the injection when given intravenously. The duration of the action varies with the dose; after very large doses it may last from ten to fifteen minutes.

A slight fall of the blood-pressure is usually observed a short time after the injection; with large doses the pressure first falls before rising, but in toxic doses ending in death the pressure falls at once definitively. When several successive injections are given the rise of the blood-pressure becomes progressively less with each injection if the dose is not increased, with the exception of the second injection the action of which is usually more marked than that of the first one. In equal doses, an intrajugular injection produces a more marked action than an intra-arterial injection.

The respiratory changes are variable according to the dose employed, as well as the phase of intoxication considered. A polypnea, occasionally very marked, is always observed directly after the injection of large doses. Certain cardiac disturbances—excessive slowness of the pulse, arrhythmia, bigeminism — are occasionally encountered after injection of the drug. Azarapetain has several times met with pulmonary edema in his experiments as I have already said, but he is not inclined to offer any opinion as to the part played by paraoxyphenylethylamine in the production of the phenomenon. He likewise noted some instances of glycosuria following injection of the drug.

The medicament also influences uterine contractions in the organ when isolated and placed in Ringer's solution maintained at a proper temperature and correctly oxygenated. It produces contractions and causes variations in their type and frequency, increasing and reinforcing them.

As to the cardiovascular, uteromotor action of paraoxyphenylethylamine, the results arrived at by Azarapetain are in conformity with those obtained by previous observers. He has been able to fix the lethal dose of the drug, which, perhaps, may be still larger if less concentrated solutions be used. Perhaps this explains why Burmann was able to inject several decigrams per kilogram of animal (rabbit) without producing death. Contrary to the results obtained by Barger and Dale, Azarapetain has not observed either lacrymation or salivation.

In comparing the action of paraoxyphenylethylamine with that of suprarenin some observers—Barger and Dale, Rosenheim, Dixon, and Taylor—have referred to the less brutal action of the former. The reaction produced by this medicament is always slower to appear, but it is also more lasting than that of adrenalin. In very large doses, paraoxyphenylethylamine exercises an injurious action on the heart which is not observed with adrenalin. In fact, a rapidly fatal dose of adrenalin invariably produces a very considerable increase of the blood-pressure before killing the animal, while paraoxyphenylethylamine lowers the pressure at once when the dose is excessive.

The cardioplegic influence of the drug under consideration was very manifest in one of Azarapetain's experiments, in which the heart of a rabbit had been arrested by a dose of thirty centigrammes per kilogramme of animal in a 10 per cent. solution and was revived by a very prolonged massage of the myocardium. Injections of adrenalin rapidly reinforce the cardiac action and raise the blood-pressure without slowing the pulse. An injection of ten centigrammes per kilogramme of animal of paraoxyphenylethylamine, on the contrary, far from reinforcing the heart, will weaken it immediately and arrest its action permanently in the lapse of about thirty seconds. To kill thus with a mean dose of the drug, the heart must of necessity be seriously involved.

Adrenalin has given satisfactory results, undoubtedly because a considerable part of the increase of the blood-pressure is provoked by vasoconstriction. But it must also be admitted that adrenalin, although it does not directly heighten the energy of

the myocardium, does not weaken it, while this weakness is at once manifest after the injection of paraoxyphenylethylamine. The vasoconstricting action of the latter drug is, at least in part, of peripheral origin. Instillation of a 1, 2, or 3 per cent. solution quite rapidly causes paleness of the injected conjunctiva of rabbits, rendered so by a previous instillation of some drops of 40 per cent. alcohol. This action recalls that which is obtained with a 1/5000 adrenalin solution.

Finally, experiments made on rabbits whose cord had been divided below the bulb, gave absolutely the same blood-pressure tracings as those obtained in intact animals. It is, therefore, evident that in a mean dose, the tonicardiac action of paraoxyphenylethylamine is accompanied by vasoconstriction of peripheral origin and in this respect the drug can be compared to adrenalin.

3. Diagnosis and Treatment of Tuberculosis of the Genito-Urinary Tract.—Arthur H. Crosbie holds that the diagnosis of tuberculosis of the kidney involves consideration of the symptoms, physical examination, examination of the urine, radiographs, pyeolgrams, and cystoscopic examination. After the diagnosis is made there is only one safe procedure and that is nephrectomy, providing the process is unilateral. If it is bilateral there is nothing left but hygienic treatment. Tuberculosis of the bladder, in the writer's experience, is always secondary to tuberculosis of the kidney. The treatment is directed to the kidney. Tuberculosis of the penis, which is rare, is apt to be confused with epithelioma, and can be differentiated surely by microscopical examination. Tuberculosis of the epididymis is always associated with tuberculosis of the seminal vesicles and prostate and in the treatment of the epididymis this should not be lost sight of. Unless there is active tuberculosis elsewhere in the body, keeping the patient pulled down, most cases do very well under hygienic treatment. The writer is very much opposed to epididymectomy for tuberculosis of the epididymis. If one is to do anything in an operative way a radical operation should be done, removing the epididymis, the entire vas and vesicles.

3. Nonleucotoxic Properties of Benzyl Benzoate.—Edwin A. Heller and Edward Steinfield state that because of the widespread use of benzyl benzoate in nearly all conditions indicating the relaxation of smooth muscle, and because of its close chemical derivation from benzol, it has appeared to them to be of interest and even advisable to investigate any possible analogy to the toxic effects of the latter. Though the untoward manifestations of benzol are varied, they selected its destructive action on leucocytes as being capable of more accurate determination and comparison with the benzoate. They used rabbits, inasmuch as the problem could not be approached from the clinical side. Several preliminary leucocyte counts were made to recognize tendency to variation in the counts, since this variability exists in rabbits. The animals were then given subcutaneous injections of benzyl benzoate in equal parts of olive oil into the loose tissues of the flanks, the preparation used being the full strength benzyl benzoate and not the alcoholic dilution, which will not mix with oil. The doses varied from one cubic centimeter to two and five-tenths cubic centimeters to the kilo of body weight, these being given in one injection, with the exception that one rabbit received four doses of twenty-five hundredths c.c. each. Two rabbits were used as controls to demonstrate the destructive effects of benzol, so that comparisons could be made with the same lot of animals under similar conditions. From these experiments the writers conclude: (1) Benzol benzoate was found to be without toxic effects upon the leucocytes of rabbits. (2) Controls of benzol showed the well-known depression of the leucocyte count. (3) A wide margin of safety is present between the therapeutic doses and the toxic doses of benzyl benzoate, based upon observations on rabbits.

5. Hypertension and Arterial Fibrosis.—C. T. Hood, in this preliminary report, expresses the opinion that there are five types of hypertension: physiological hypertension, hypertension in the young, arterial fibrosis, chronic nephritis, and hyperthyroidism. These are briefly discussed. Increased tissue fluid pressure causes, first, increased capillary resistance; second, hypertrophy of the heart; third, fibrosis of the arteries. The practical application of these facts involves the question, What can and does increase the body fluid pressure in the capillaries? He believes, from certain experiments, that sodium chloride in the tissues brings about this condition. That salt will hold back the body fluids has been abundantly proved, and the clinical results obtained from this fact can be proved by anyone. If the body fluids contain an abnormal amount of sodium chloride for the individual, the intratissue fluid pressure is increased, capillary resistance is raised, and ultimately there is hypertrophy of the heart, with arterial fibrosis. The elimination of the chlorides is an unsolved problem. So far, he has found but one drug, potassium nitrate, which in any way increases the elimination of the chlorides, and this drug is effective in not more than seventy-five per cent. of the cases. Large doses of potassium nitrate increase the volume of urine, but not the twenty-four hour output of the chlorides, while smaller doses of the drug, as five grains to the ounce, and fifteen drops in a half glass of water, three times a day, will not increase the volume of urine, but will increase the amount of chlorides up to the normal, and maintain this until the individual is filtered of his excess chlorides. In chronic nephritis, potassium nitrate is of little avail, except in the true arteriosclerotic nephritis. In chronic nephritis, other than the arteriosclerotic type, when the urine is of a low fixed specific gravity, with the kidney function from five to fifteen per cent., the administration of eserine, one-fortieth of a grain three times a day, will increase the chloride elimination for several weeks, then the chlorides will fall to almost nothing, and the nitrogen and urea elimination will increase, often to a marked extent. It is now generally conceded that the iodides or iodine have no place in the treatment of hypertension or arterial fibrosis. The salt poor and salt free diet have been used for some years by many clinicians in the treatment of chronic nephritis, but salt free diet has never been pushed, so far as he knows, to the point of the removal of the surplus sodium chloride from the body, and keeping the tissue sodium chloride content at the physiological amount. Herein lie the possibilities. Hood expresses the view that the internal secretions do not alter his hypothesis.

6. **Indifference of the Laryngologist Toward Tuberculous Laryngitis and the Tuberculosis Problem.** William V. Mullin has found, upon investigation, that some laryngologists claim that they see very little tuberculous laryngitis in their part of the country—which means that they are not making the diagnosis. Some are afraid of becoming infected themselves while examining or treating this condition. Others prefer to send the patients to a sanitarium. In order to ascertain the situation at sanitariums throughout the country, the writer sent a questionnaire to all tuberculosis sanitariums listed in the directory published by the National Association for the Study and Prevention of Tuberculosis. His deductions from the answers are in part as follows: The institutions constituting the 21 per cent. which do not admit known cases of laryngeal tuberculosis are adding to the number of patients who are endeavoring to seek recovery from tuberculosis of the throat by going to the private office of the physician or to the free dispensaries; whereas, if they are to gain any results at all, they should be in bed carrying out the absolute rest cure. One does not leave the diagnosis and treatment of ear cases, sinus conditions, or other diseases of the larynx, to a general man, so why leave to him laryngeal tuberculosis? The greatest care should be taken to rule out and prevent every irritation from above, thereby greatly lessening cough and preventing complications. In the 74 per cent. of institutions in which patients are not examined by a competent laryngologist the chances for making a diagnosis of early infiltrations in the larynx are greatly lessened. Men who are doing tuberculosis work are looking to the laryngologists for some definite ideas on this disease, and, in the writer's opinion, are not receiving the aid they should have. A more active interest in tuberculosis should be taken by laryngologists. There should be more thorough and uniform teaching of the diagnosis of this disease, and it should be carried on in such a way that the student will have opportunity to examine large numbers of incipient cases, and to see these repeatedly, and thus familiarize himself with the laryngeal image seen in tuberculosis as compared with that found in other allied conditions.

7. **Soaps in Relation to Their Use for Hand Washing.**—John F. Norton reports the results of experiments undertaken to determine four things: First, the relative efficiency of various soaps in removing bacteria from the hands. Second, the relative germicidal power of the soap solutions obtained in washing toward bacteria removed from the hands. Third, the bacterial condition of the hands after washing, i.e., whether syerile or not. Fourth, the effect of the soap, if any, remaining on the hands, comparing the action of different soaps in this respect. Twelve soaps were used in the experiments, varying from the cheapest toilet soaps to the expensive so-called antiseptic and germicidal soaps. His conclusions from the study follow: Sterile hands are not obtained in the ordinary process of hand washing. More bacteria were found to be removed by the ordinary toilet soaps than by the special soaps. In other words, the cleansing properties of a soap are more important than its "germicidal" or "antiseptic" constituents. The soap solutions obtained in hand washing are of no practical germicidal or antiseptic value. The soap left on the hands after washing has no germicidal action. In the whole process of hand washing done in the usual manner, the special so-called "germicidal" or "antiseptic" soaps exhibit none of these properties. Therefore these terms are not proper to use in connection with soaps. Since the hands may serve as a medium for the conveyance of bacteria in infectious diseases, it is important to remove these bacteria; and this may be done by the ordinary toilet soaps as effectively, if not more so, as by the special brands of so-called "antiseptic" or "germicidal" soaps.

3. **The Physical Element in the Psycho-Neuroses.**—Judson S. Bury, confining his remarks to genuine cases of the neuroses, holds that the difficulty in discriminating between malingering and a true neurosis is very great, and one is apt to be biased by personal feeling toward the patient. True malingering—that is, conscious simulation—is rare. It is, however, often combined with true hysteria, or unconscious simulation, and it is such combinations that lend themselves most readily to dramatic cures. The writer deals with the underlying physical basis of the neuroses, because there seems to be a tendency to lay undue stress on the psychical factor. At any rate, it seems unlikely that molecular disturbances of the nervous system and altered blood states largely account for the long duration of many cases and for the great tendency for symptoms to relapse on the slightest provocation, whether that be undue exertion, loud sudden noises, or family or business anxieties. In the most common type of case better results will be attained by fresh air, sunlight, cheerful surroundings, and light work, than by continuous searching for a hidden mental conflict. Of the value of psycho-analysis in certain intractable cases where there are reasons for suspecting a repressed memory or complex, Bury does not attempt to express an opinion. Nor is he tempted to undertake the necessary investigations when he reads that a three years' study of the subject is essential, and that to unravel a complex, to trace some of its elements back, possibly to some incident in childhood, often a very muddy one, may occupy the constant attention of the psycho-analyst for at least several months, and sometimes for a year and even longer.

1. **Adenomata of the Carotid Gland.**—Mont R. Reid finds that the total number of reported cases of tumors of the carotid body is sixty-six, to which he adds three cases from Professor Halsted's clinic. From his study of the reported cases and of those which he has personally studied he formulates the following summary: (1) The slow growing pigmented tumor of the carotid gland, heretofore described as "carotid body tumor" is a simple hyperplasia of a part or all of the normal gland; it should be designated as an adenoma or hyperplasia of the carotid body. In rare instances a malignant condition may develop in it. (2) A "potato tumor of the neck" may be a primary sarcoma or carcinoma of the carotid body. (3) The relation of the common carotid artery to enlargements of the carotid gland ought to help us in arriving at a correct diagnosis. This artery is caught and carried laterally or anteriorly so that it and its branches may often be readily felt on the surface of the tumor. (4) A bulging of the pharyngeal wall and a paralysis of a vocal cord are frequently observed in an enlargement of the carotid body. The paralysis may be detected only by direct examination of the cords, inasmuch as disturbances of speech do not usually occur. (5) Yellowish pigmentation of the body, flushing of the head and neck and a slow, somewhat apathetic state of mind may result from hyperplasia of the carotid gland. (6) The mortality of operations for hyperplasia of the carotid body has been very high. Preliminary ligation, partial or complete, of the carotid artery, and careful hemostasis at the second operation may reduce it materially. (7) In some cases in which an operation is imperative on account of the size of the growth it may be wiser to do a decompressive operation than to attempt extirpation of the tumor. Then, after the tumor dislocates laterally and becomes more superficial, its removal will be easier and safer, particularly if the artery has been tied at the time of decompression.

Finska Läkaresällskapets Handlingar.

March-April, 1920, lxii, 3-4.

Occurrence of Hairs in Supernumerary Nipples.—Kajava has made a mass investigation of supernumerary nipples in Finland and finds that hairy ones are not uncommon, being present in over 12 per cent. of those examined. As a rule the hairs sprout from the summit of the nipple in both types of the anomaly—supernumerary breast proper and supernumerary nipple, and even in the socalled areolar hyperthelia. In the latter form the nipple is quite flat. The structure of the hairs in these localities is typical although sometimes the follicles are unusually wide. In more detail the total number of subjects presenting supernumerary formations was 345 and the ratio of breasts to nipples was about 2½ to 1. The total number presenting hairs was 42, this ratio being about 3 to 1.

Treatment of Postdiphtheritic Stenosis of the Larynx and Trachea.—Bardy cites 4 cases of these sequelæ in children between the ages of 1½ and 4 years in which he employed the Thost-Uchermann method, the duration of treatment being from 5 to 15 months. The voice is rough but distinct and two of the children are now attending school. Three others are under the same treatment. The author says that the Schmiegelow method of fixation has been tested with unsatisfactory results, probably because of the poor quality of war rubber.
